J. Fassbender, V. Heera, M. Helm, P. Zahn
The cover shows a schematic of the concept of a spin valve device produced using ion-beam irradiation. Consider a mesoscopic Fe<sub>60</sub>Al<sub>40</sub> wire, seen in the background, composed of well-ordered atomic planes of Fe (blue spheres) and Al (red spheres) atoms. This chemically ordered structure is non-magnetic, but it transforms to a ferromagnetic state when the atomic arrangement is disordered. To achieve this transformation locally at the nanoscale, resist masks were placed on the wire (middle row). The wire was irradiated with Ne<sup>+</sup> ions at an energy of 20 keV and a low fluence of 6 x 10<sup>14</sup> ions cm<sup>-2</sup>. The ions penetrate the ordered lattice and randomize the atomic arrangement, thereby magnetizing the disturbed regions. Regions covered by the resist mask are not influenced by the energetic ions, and remain non-magnetic. The resulting tailored magnetic stripes (front row) are isolated from each other by sub-50 nm non-magnetic spacers. The magnetization directions of such stripes can be aligned using external magnetic fields. As an electric current traverse through these stripes, spin-polarization and spin-scattering phenomena occur, causing the electrical resistance to be dependent on the stripe magnetization directions. Such devices, known as spin valves, are crucial for sensing magnetic fields, for instance in data-storage devices. Future magneto-transport devices could potentially be produced using ion-beam irradiation. Image: HZDR / S. Münster

Preface by the directors

This past year 2014 was the year when we finally completely arrived as a “full member” in the Helmholtz Association. This is related to the successfully passed research evaluation in the framework of the Program Oriented Funding (POF), which will give us a stable and predictable funding for the next five years (2015 – 2019). This is particularly true for our large-scale user facilities, like the Ion Beam Center (IBC) and the electron accelerator ELBE with the free-electron laser. Most of our activities are assigned to the program “From Matter to Materials and Life” within the research area “Matter”, in cooperation with several other German Helmholtz Centers. Our in-house research is performed in three so-called research themes, as depicted in the schematic below. What is missing there for simplicity is a small part of our activities in the program “Nuclear Waste Management and Safety” within the research area “Energy”.

Our research and facilities were well appreciated by the evaluation committee, who made the following judgement about the Ion Beam Center:

“The Ion Beam Centre (IBC) of HZDR is an internationally leading ion-beam facility (with ion energies ranging from several eV to several tens of MeV). At both the national and international level it is one of the key players and is unique in its kind. The synergy between forefront research and user service has been leading to a very good publication output for both in-house research and user research. …

The very broad range of beam energies, the versatility of techniques and applications – both for ion beam modification of materials and for ion-beam analysis – makes the IBC unique in its kind. …

The strength of IBC is that its activities are based on a combination of forefront research and user service, which mutually interact in synergy and strengthen one another. In turn, this synergy has been leading to a very good publication output for both in-house research and user research.”

In order to make our Annual Report a bit more compact, we have decided to include only four full journal papers this year. This was also triggered by the fact that our publication activities have turned out be become more diverse, in more diverse journals than in the past, and often through longer
papers, which would be too long to reprint them here. However, apart from the constantly quantitatively high publication output, we succeeded to publish in excellent journals such as Nature Physics, Nano Letters and Physical Review Letters, in fields as diverse as ion beam physics, magnetism and terahertz spectroscopy.

Two of our scientists, Dr. Artur Erbe and Dr. Alexej Pashkin obtained their Habilitation in 2014, both at University of Konstanz. For the first time, we are hosting an Emmy Noether Young Investigator Group funded by the Deutsche Forschungsgemeinschaft (DFG); the group works on the hot topic of magnonics and is headed by Dr. Helmut Schultheiß.

Finally we would like to cordially thank all partners, friends, and organizations who supported our progress in 2014. Special thanks are due to the Executive Board of the Helmholtz-Zentrum Dresden-Rossendorf, the Minister of Science and Arts of the Free State of Saxony, and the Minister of Education and Research of the Federal Government of Germany. Numerous partners from universities, industry and research institutes all around the world contributed essentially, and play a crucial role for the further development of the institute. Last but not least, the directors would like to thank again all IIM staff for their efforts and excellent contributions in 2014.

Carrier dynamics in Landau-quantized graphene featuring strong Auger scattering

Martin Mittendorff1,2,*, Florian Wendler3, Ermin Malic3, Andreas Knorr3, Milan Orlita4,5, Marek Potemski6, Claire Berger6,7, Walter A. de Heer6,8, Harald Schneider1, Manfred Helm1,2 and Stephan Winnerl1,*

The energy spectrum of common two-dimensional electron gases consists of a harmonic (that is, equidistant) ladder of Landau levels, thus preventing the possibility of optically addressing individual transitions. In graphene, however, owing to its non-harmonic spectrum, individual levels can be addressed selectively. Here, we report a time-resolved experiment directly pumping discrete Landau levels in graphene. Energetically degenerate Landau-level transitions from \( n = -1 \) to \( n = 0 \) and from \( n = 0 \) to \( n = 1 \) are distinguished by applying circularly polarized THz light. An analysis based on a microscopic theory shows that the zeroth Landau level is actually depleted by strong Auger scattering, even though it is optically pumped at the same time. The surprisingly strong electron-electron interaction responsible for this effect is directly evidenced through a sign reversal of the pump-probe signal.

Transport experiments on graphene in magnetic fields have revealed a number of fascinating phenomena, such as quantum ratchet effects, the Hofstadter butterfly and the fractional quantum Hall effect. The anomalous quantum Hall effect, which is a consequence of a Landau level (LL) at zero energy in graphene (Fig. 1a), is considered a hallmark of the Dirac-fermion nature of charge carriers in graphene. The non-equidistant LL structure has been observed in various continuous-wave (cw) magneto-spectroscopy experiments, which provided evidence for the Dirac-cone band structure at various energies. Furthermore, this technique allows one to determine the Fermi velocity and to identify graphene of extremely high quality. The observation of a giant Faraday rotation of light passing through graphene in magnetic fields as well as the demonstration of tunable THz detectors highlights the application potential of graphene in magneto-optic devices. For more sophisticated applications such as light emitters, however, a detailed knowledge of the carrier dynamics is required.

Although the relaxation dynamics in graphene at zero magnetic field has been studied intensively, there is so far only one time-resolved spectroscopy study in the presence of a magnetic field, in which a pump probe study was performed at high energies corresponding to the excitation of a quasi-continuum of LLs characterized by a LL separation smaller than the LL broadening. The observed increase in relaxation time at enhanced magnetic fields was attributed to a suppression of Auger processes. The role of Auger scattering bridging the valence and conduction bands and changing the number of charge carriers has been controversially discussed for graphene in the absence of magnetic field. Charge carriers fulfill energy and momentum conservation for possible combinations of pumping and probing with left- and right-circularly polarized radiation, which allows one to selectively address the degenerate LL transitions (Fig. 1a). Our main observation is that for one of the four possible combinations of pumping and probing with left- and right-circularly polarized radiation, the differential transmission signal (DTS) shows the opposite sign with respect to the signal.

The time-resolved experiments were performed on multilayer ($\sim 40$ layers) epitaxial graphene (MEG) grown by thermal decomposition on the C-terminated face of SiC (ref. 29). The decoupled nature of the layers of the sample was evidenced by Raman spectroscopy$^{30}$ and cw magneto-spectroscopy$^{9}$. The majority of graphene layers exhibit weak doping$^{11,18}$, although layers close to the interface of SiC are strongly n-doped$^{16,31,32}$. In our sample the majority of layers is n-type, with an electron concentration $N_a = 10^{10}$ cm$^{-2}$ (see details of sample doping in Methods). The free-electron laser FELBE delivered radiation pulses with a duration of 2.7 ps (full-width at half-maximum, FWHM) and a photon energy of 75 meV. Various pump–probe experiments were performed, involving linear polarization as well as left- and right-circularly polarized radiation for pumping and probing. A simplified sketch of the experiment with linearly polarized radiation is shown in the inset of Fig. 1b. Details on the experimental configuration can be found in the Methods. In all experiments, the sample temperature was kept at 10 K in a cryostat that allows the application of magnetic fields up to 7 T.

In the following, induced transmission transients (Fig. 1b) are analysed. The features of the induced transmission amplitudes (Fig. 1d) and the initial relaxation time (Fig. 1e) are identified by comparing their $B$-field dependence to the dynamic conductivity of a graphene layer (Fig. 1c). The dynamic conductivity, which is proportional to the absorption, is calculated using the Kubo formalism$^{9}$, considering the dipole radiation selection rule $|\Delta n| = 1$. A width of 7 meV is chosen in accord with cw magneto-spectroscopy data$^{11}$. The calculation allows us to attribute peaks in the induced transmission to the interband transitions $L_{L-1} \rightarrow L_{L-1}$, $L_{L-2} \rightarrow L_{L-1}$, $L_{L-3} \rightarrow L_{L-2}$, and $L_{L-4} \rightarrow L_{L-3}$, in weakly n-doped graphene layers (Fig. 1c,d). On resonance with these transitions the induced transmission is enhanced. The strongest resonant enhancement (by factor of 2.5 relative to the signal at $B = 0$) is observed for the energetically lowest transition (Fig. 1d). That note to the vanishing density of states between LLs (for example, for $1 T < B < 3 T$) the pump–probe signal is expected to vanish in this region. The observed non-zero signals in the experiment most likely stem from intraband LL transitions in the highly doped graphene layers close to the interface with the SiC substrate. In cw magneto-spectroscopy experiments, broad absorption features from doped layers have already been observed$^{33,34}$, supporting this interpretation.
For magnetic fields below 3 T the relaxation dynamics is characterized by a single exponential decay with a time constant of about 20 ps (Fig. 1b,c). For higher magnetic fields an additional fast decay component is observed. At 4.2 T the LL \( \sigma_1 \to \sigma_0 \) transition is resonantly excited. Here, we observe a fast initial decay of \( \tau = (3 \pm 1) \) ps—that is, the initial dynamics is almost one order of magnitude faster than the slow component. This very fast decay of the pump–probe signal is surprising, as the LL spacing does not match the energy of optical phonons and, thus, the carrier–phonon interaction is missing; this is the initial dynamics we are trying to observe. One can distinguish two counteracting Auger scattering processes, redistribution of carriers, giving rise to a different sign of the DTS.

To shed light on the nature of the observed fast population change responsible for the acceleration of the carrier dynamics, we employ circularly polarized radiation (\( \sigma^+ \) and \( \sigma^- \)-radiation). We record DTS successively for all four combinations of pumping and probing with \( \sigma^+ \) and \( \sigma^- \)-radiation (see Fig. 2a). According to the optical selection rules, \( \sigma^- \)-radiation pumps the \( \sigma^- \)-polarized graphene—this is true for initial occupations \( \rho_0 = 0.5 \), \( \sigma^+ = 1 \) and \( \sigma^- = 0 \). This system is fully symmetric with respect to electrons and holes and, consequently, with respect to excitation by \( \sigma^+ \) and \( \sigma^- \)-radiation. In this case, assuming that the dynamics is determined only by Pauli blocking, one expects positive DTS (increased transmission) for pumping and probing with the same polarization state and negative pump–probe signals (increased absorption) for pumping and probing with the opposite polarization state (see Fig. 2b). The signals within one pair of similar and opposite polarization feature similar amplitudes. For doped graphene the electron–hole symmetry is broken; hence, the absolute values of the induced transmission differ for the four different polarization combinations. Nevertheless, this does not change the expected DTS sign discussed above. Furthermore, energy relaxation via phonons and defect–mediated phonon scattering have no influence, as they are much too slow to relax the carrier distribution back into the equilibrium state.

The experiments show the following behaviour: the DTS for pumping with \( \sigma^- \)-radiation (Fig. 2c,e) exhibits a fast initial decay, of the order of the pulse duration, and a slower relaxation component. The sign of the DTS is in accord with the expectation considering the pump scheme depicted in Fig. 2b. In particular, negative DTS is obtained with \( \sigma^- \)-pumping and \( \sigma^- \)-probing (Fig. 2f). However, an unexpected positive signal is observed, indicating that a strong redistribution of carriers must take place, beyond the effect induced by the photon field. A possible explanation is the \( \sigma^+ \)-polarized pulse with a width of \( 2 \) ps, a pump fluence of \( 0.1 \) \( \mu \)J cm\(^{-2} \) and an excitation energy of 75 meV, corresponding to a filling of LL\( _0 \) of 64% at 4.2 T. (At \( B = 0 \) this would correspond to a Fermi energy of 28 meV, see also Methods for details of sample doping.) First, we optically generate a non-equilibrium carrier distribution by applying \( \sigma^+ \) pump and \( \sigma^- \) probe polarization, with a width of \( 2 \) ps, a pump fluence of 0.1 \( \mu \)J cm\(^{-2} \) and an excitation energy of 75 meV, corresponding to the experimental realization. Then, we investigate the temporal evolution of the microscopic polarization \( \rho_{\sigma^+} \) and the carrier occupations \( \rho_\sigma(t) \) in the involved LLs. We focus on the carrier dynamics within the energetically lowest LLs.

The calculated differential transmission reproduces well all qualitative features of the measured DTS (see Fig. 2d,h.i). For pumping with \( \sigma^- \)-radiation, the theoretical curves show the same surprising result as observed in the experiment, namely the unexpected positive signal for probing with \( \sigma^- \)-radiation and the initially positive and subsequently negative signal for probing with \( \sigma^+ \)-radiation (Fig. 2h,j). We note that by artificially weakening the electron–electron coupling the expected negative DTS is obtained for pumping and probing with opposite polarization (see Supplementary Methods), confirming that Auger processes are indeed the reason for the surprising positive DTS observed in the experiment, as further discussed below. Note that for pumping with \( \sigma^- \)-radiation, the signals are in accord with the expectations considering the optical selection rules; however, when probing with \( \sigma^- \)-radiation a plateau after the initial peak is observed in the DTS (Fig. 2f). This is an indication that also in this configuration the underlying dynamics is more complex than a simple relaxation to the equilibrium. The processes leading to the plateau are further discussed in the Supplementary Methods.
Figure 2 | Pump–probe spectroscopy on graphene with circularly polarized radiation. a, Configuration of the experiments for pumping and probing with $\sigma^-$ and $\sigma^+$-radiation. b, In the absence of strong Auger scattering, pumping and probing with the same polarization results in induced transmission, whereas applying opposite polarization results in induced absorption. c,e,g,i, Experimental pump–probe signals for all four combinations of pumping and probing with $\sigma^-$ and $\sigma^+$-radiation. Blue and red shaded regions highlight positive and negative DTS, respectively. d,f,h,j, Differential transmission calculated by microscopic theory for all four combinations of pumping and probing with $\sigma^-$ and $\sigma^+$-radiation. The photon energy is 75 meV and $B = 4.2$ T for all panels. a.u., arbitrary units.

As our calculations give microscopic access to the time-resolved populations of the LLs, we can reveal the underlying elementary scattering processes responsible for the observed and theoretically predicted surprising features in the differential transmission spectra. Our calculations clearly reveal that Auger processes play the crucial role. They give rise to an efficient redistribution of carriers in the energetically equidistant levels LL$_0$, LL$_1$ and LL$_{-1}$. The time-resolved occupations of the energetically lowest LLs are
shown in Fig. 3: for pumping with $\sigma^-$-radiation, optical excitation depopulates LL$_1$, leading to a decrease of $\rho_1(t)$ (Fig. 3b). At the same time, LL$_1$ becomes populated, resulting in an increase of $\rho_0(t)$. In the case of pumping with $\sigma^+$-radiation, inward Auger scattering dominates, because it counteracts the optical pumping (Fig. 3a). This effect causes the decreased occupation of LL$_{-1}$, which is not affected by the optical pumping (Fig. 3b). In contrast, for pumping with $\sigma^+$-radiation, outward Auger scattering dominates over inward processes (Fig. 3c). In n-type graphene, the Auger scattering is so efficient that, after an initial increase of $\rho_0(t)$ due to the optical pumping, an Auger-induced decrease is found (Fig. 3d). As a result, we do not observe enhanced absorption and negative DTS as expected for pumping with $\sigma^+$ and probing with $\sigma^-$-radiation (Fig. 2b), but rather a positive pump–probe signal (see Fig. 2g,h). The Auger scattering efficiently populates LL$_1$, giving rise to absorption bleaching of the $\sigma^+$-probe pulse and resulting in positive differential transmission. The initial increase and subsequent decrease of the occupation of LL$_0$ is responsible for the sign reversal of the DTS for pumping and probing with $\sigma^+$-radiation (see Fig. 2i,j; for a detailed explanation see Supplementary Methods).

It is instructive to separately consider the effects of carrier–carrier and carrier–phonon scattering on the level occupation (see grey lines in Fig. 3b,d). Pure carrier–phonon scattering leads to population changes only in the LLs that are directly affected by the optical pumping. Consequently, in this case the population of LL$_0$ is increased by $\sigma^+$ pumping (Fig. 3d). In contrast, pure carrier–carrier scattering results in a dynamics that is qualitatively very similar to the full dynamics. The only difference is that without phonon scattering the level occupation does not relax back to the initial equilibrium state, because the energy added by the pump pulse cannot be removed from the electronic system. This leads to a new hot-carrier equilibrium state that is characterized by a decreased population of both LL$_{-1}$ and LL$_1$ as well as an increased population in LL$_0$ for pumping with both $\sigma^-$ and $\sigma^+$ radiation (Fig. 3d).

Note that for intrinsic graphene the effect of the Auger processes on the carrier distribution is not strong enough to change the sign of the DTS. Even small doping breaks the electron–hole symmetry and, consequently, the balance between outward and inward Auger scattering. This results in the surprising effects observed. The same effects observed for n-doped graphene under pumping with $\sigma^-$-radiation occur for p-doped graphene under pumping with $\sigma^+$-radiation. Further reasoning behind the unexpected DTS sign in Fig. 2g can be given using simple thermodynamic arguments. The observed Auger scattering represents a very efficient (elastic) relaxation process that drives the system perturbed by the pump pulse towards the new equilibrium at higher electron temperature. This redistribution is visible, in particular, in the occupation of LL$_0$, which increases with increasing electron temperature for p-doped graphene, but always decreases in the n-doped system. Counter-intuitively, the latter happens even when LL$_0$ is directly pumped. The positive DTS sign for a $\sigma^-$-polarized probe pulse in Fig. 2g...
thus directly reflects the pump-induced depopulation of LL0. More detailed considerations described in the Supplementary Methods reveal that positive DTS signals for σ−-polarized probe pulses are expected when the initial occupation of LL0 exceeds a threshold value of $2 - \sqrt{2} \approx 0.59$.

Our study conclusively shows that carrier–carrier scattering is the predominant mechanism for carrier redistribution in Landau-quantized graphene. Scattering with optical phonons, on the other hand, is expected to be strongly suppressed unless the LLs are resonant with the optical phonon energy $\hbar \omega$. In the experiments performed, we find only a moderate increase of the decay time with the absence of magnetic fields. The role of these phonon-related processes is understood by defect-assisted scattering with acoustic phonons, which has been identified as an important scattering mechanism in the absence of magnetic fields. The role of these phonon-related relaxation channels for Landau-quantized graphene still needs to be thoroughly investigated in future studies.

In conclusion, our results show that Landau-quantized graphene is ideal for the investigation of strong carrier–carrier scattering processes. The levels LL−1, LL and LL0 are decoupled from the remaining spectrum both with respect to optical excitation and scattering. The three equidistant but optically selectively addressable levels are an ideal system to study energy-conserving carrier–carrier scattering processes. The possibility of polarization-sensitive induced absorption and induced transmission can be applied for concepts of optical switching with high functionality. In quantum information processing, circularly polarized radiation is often used to address quantum bits. The switching in Landau-quantized graphene can be controlled all-optically by the polarization state of the radiation. Electric gating allowing one to switch from n-type to p-type graphene would add even more functionality. Furthermore, the non-equidistant Landau spectrum of graphene offers the possibility of developing a tunable laser. For example, pumping the LL1, LL2 → LL0 transition should result in population inversion between LL1 and LL2. On the other hand, Auger scattering may be directly exploited to realize carrier multiplication in Landau-quantized graphene. To this end, pumping the LL−1, LL0 transition Auger scattering between the equidistant levels LL−1, LL0 and LL can facilitate carrier multiplication.

Methods

Pump–probe spectroscopy. The free-electron laser FELBE provided frequency-tunable Fourier-limited radiation pulses. In the experiments described in the paper a photon energy of 75 meV was chosen. The pulse duration of the 75 meV pulses was 2.7 ps (repetition rate 13 MHz). The pulses were split into pump and probe pulses by a pellicle beam splitter. The duration of the 75-meV pulses was 2.7 ps (repetition rate 13 MHz). The pulses were split into pump and probe pulses by a pellicle beam splitter. The polarization of the radiation. Electric gating allowing one to switch from n-type to p-type graphene would add even more functionality. Furthermore, the non-equidistant Landau spectrum of graphene offers the possibility of developing a tunable laser. For example, pumping the LL1, LL2 → LL0 transition should result in population inversion between LL1 and LL2. On the other hand, Auger scattering may be directly exploited to realize carrier multiplication in Landau-quantized graphene. To this end, pumping the LL−1, LL0 transition Auger scattering between the equidistant levels LL−1, LL0 and LL can facilitate carrier multiplication.

Microscopic modelling. In this study, we focus on the impact of Coulomb interactions and include carrier–phonon scattering on a phenomenological level. To this end, the full scattering rate $S_{\sigma}(\omega)$, including Pauli-blocking terms and phonon occupations is considered, while the corresponding electron–phonon matrix elements are adjusted to the experimentally observed decay. The phonons are assumed to be in equilibrium with a phonon bath and their occupations are described by the Bose–Einstein distribution. In contrast, the Coulomb interaction is entirely considered on a microscopic footing. We also take dynamical screening of the Coulomb potential into account by evaluating the dielectric function $\varepsilon(\omega)$ in the random phase approximation, following the approach of refs 37,43. The broadening is calculated self-consistently, taking into account scattering of electrons on an impurity potential with a Gaussian white noise distribution. This electron-impurity scattering yields the dominant contribution to the dephasing $\Gamma(\omega)$ of the microscopic polarization, which also comprises contributions of Coulomb- and phonon-induced many-particle scattering.

Sample doping. MEG samples grown on the C-terminated face of SiC consist of five or more layers. The non-equidistant Landau spectrum of graphene is thus directly reflected in the pump-induced depopulation of LL0. More detailed considerations described in the Supplementary Methods reveal that positive DTS signals for $\sigma^-$-polarized probe pulses are expected when the initial occupation of LL0 exceeds a threshold value of $2 - \sqrt{2} \approx 0.59$.

Our study conclusively shows that carrier–carrier scattering is the predominant mechanism for carrier redistribution in Landau-quantized graphene. Scattering with optical phonons, on the other hand, is expected to be strongly suppressed unless the LLs are resonant with the optical phonon energy $\hbar \omega$. In the experiments performed, we find only a moderate increase of the decay time with the absence of magnetic fields. The role of these phonon-related processes is understood by defect-assisted scattering with acoustic phonons, which has been identified as an important scattering mechanism in the absence of magnetic fields. The role of these phonon-related relaxation channels for Landau-quantized graphene still needs to be thoroughly investigated in future studies.

In conclusion, our results show that Landau-quantized graphene is ideal for the investigation of strong carrier–carrier scattering processes. The levels LL−1, LL and LL0 are decoupled from the remaining spectrum both with respect to optical excitation and scattering. The three equidistant but optically selectively addressable levels are an ideal system to study energy-conserving carrier–carrier scattering processes. The possibility of polarization-sensitive induced absorption and induced transmission can be applied for concepts of optical switching with high functionality. In quantum information processing, circularly polarized radiation is often used to address quantum bits. The switching in Landau-quantized graphene can be controlled all-optically by the polarization state of the radiation. Electric gating allowing one to switch from n-type to p-type graphene would add even more functionality. Furthermore, the non-equidistant Landau spectrum of graphene offers the possibility of developing a tunable laser. For example, pumping the LL1, LL2 → LL0 transition should result in population inversion between LL1 and LL2. On the other hand, Auger scattering may be directly exploited to realize carrier multiplication in Landau-quantized graphene. To this end, pumping the LL−1, LL0 transition Auger scattering between the equidistant levels LL−1, LL0 and LL can facilitate carrier multiplication.

Supporting Information

ABSTRACT: Ferromagnetism in certain alloys consisting of magnetic and nonmagnetic species can be activated by the presence of chemical disorder. This phenomenon is linked to an increase in the number of nearest-neighbor magnetic atoms and local variations in the electronic band structure due to the existence of disorder sites. An approach to induce disorder is through exposure of the chemically ordered alloy to energetic ions; collision cascades formed by the ions knock atoms from their ordered sites and the concomitant vacancies are filled randomly via thermal diffusion of atoms at room temperature. The ordered structure thereby undergoes a transition into a metastable solid solution. Here we demonstrate the patterning of highly resolved magnetic structures by taking advantage of the large increase in the saturation magnetization of Fe60Al40 alloy triggered by subtle atomic displacements. The sigmoidal characteristic and sensitive dependence of the induced magnetization on the atomic displacements manifests a sub-50 nm patterning resolution. Patterning of magnetic regions in the form of stripes separated by ~40 nm wide spacers was performed, wherein the magnet/spacer/magnet structure exhibits reprogrammable parallel (↑/spacer/↑) and antiparallel (↑/spacer/↓) magnetization configurations in zero field. Materials in which the magnetic behavior can be tuned via ion-induced phase transitions may allow the fabrication of novel spin-transport and memory devices using existing lateral patterning tools.

KEYWORDS: Phase-transitions, chemical disorder, magnetic patterning, magnetic nanostructures, memory devices

Fabrication of highly resolved magnetic objects is of vital importance for the functioning of devices such as patterned data storage media and magneto resistive random access memories (MRAMs). Continued increase of data storage capacity may depend on the ability to fabricate magnetic nanoelements on large wafers using commercially viable processes. A route to large-area patterning of magnetic nanostructures is the localized exposure of materials to accelerated ions, where the magnetic properties of regions selectively exposed are modified. Typically, irradiation with ions causes disorder within the material and this modifies parameters such as magnetic anisotropy axes, magnetic damping, and interlayer exchange coupling. Modulation of these secondary parameters may not be sufficient to fabricate, for instance, spin-transport devices where it is crucial to decouple neighboring ferromagnetic regions with narrow nonmagnetic spacers. Therefore, it is essential to obtain materials in which large variation of intrinsic properties such as the saturation magnetization \( M_s \) is possible at high lateral resolution.

Ion-induced modification of \( M_s \) usually occurs through suppression of the magnetic phase and can be achieved by destroying the structure through large atomic displacements, alloying with the ion species, or amorphization by intermixing with a cap layer. These destructive processes require excessively high ion-fluences (typically \( \sim 10^{16} \text{ to } 10^{19} \text{ ions cm}^{-2} \) and may result in the formation of magnetic inhomogeneities, thereby lowering the resolution of patterning. Furthermore, the destructive process hinders the use of a focused ion-beam as a stylus for direct writing of magnetic patterns. Some processes can be nondestructive, for instance, where the incident ions chemically react with the material to form ferromagnetic phases locally, however, owing to

stoichiometrical reasons large ion fluences may be required.\textsuperscript{18} In certain alloys, ferromagnetism can be induced by increasing chemical disorder,\textsuperscript{19,20} a property that could be ideal for writing magnetic patterns using ions. However, these systems have yet to be exploited for high-resolution patterning, partly due to the insufficient sensitivity of the induced magnetization on the disorder. In all types of ion-induced modifications, ions penetrate a material in a quasi-Gaussian distribution that could be translated into a depth-varying magnetization. Ions are also scattered laterally, causing modifications to the material underneath a shadow-mask, thereby blurring the intended magnetic pattern and imposing a limit on the patterning resolution.

In this Letter, we demonstrate sub-50 nm resolution magnetic patterning by employing a chemically ordered Fe\textsubscript{60}Al\textsubscript{40} alloy, in which the M\textsubscript{s} is drastically increased via ion-induced disordering. The increase in M\textsubscript{s} is attributable to an increase in the Fe–Fe nearest neighbors (n-ns) due to disorder. We show that relatively few displacements of Fe and Al atoms are sufficient to increase the saturation magnetization by a factor of 40. This sensitivity of the induced magnetization to the atomic displacements implies that homogeneously magnetized regions can be obtained using fewer ions (∼10\textsuperscript{14} ions cm\textsuperscript{-2}), as compared with destructive or chemically reactive processes. Furthermore, under the given ion-energy and -fluence conditions, the homogeneously magnetized objects can be obtained with limited lateral scattering: restriction of lateral scattering significantly enhances the patterning resolution, that is the closest lateral distance at which neighboring magnetic objects can be placed while maintaining magnetic isolation.

High-resolution magnetic patterning is proven experimentally by the fabrication of magnetically decoupled stripes separated by 40 nm wide spacers on a Fe\textsubscript{60}Al\textsubscript{40} wire. The decoupling enables the stabilization of binary magnetic states, that is parallel and antiparallel moment configurations of neighboring stripes in remnant fields. The existence of binary magnetic states is prerequisite for the operation of spin-valves and is obtained in a device with narrow cross-section. Spin-transport devices require narrow cross sections for achieving high-current densities. Devices with narrow cross sections are usually fabricated vertically in the form of multilayered pillar structures that require complicated process steps and are difficult to electrically contact. Achieving the so-called “current-perpendicular-to-plane” (CPP) geometry within two lateral patterning steps could greatly simplify the fabrication of spin-transport devices. Moreover, materials exhibiting disorder-induced ferromagnetism may also be highly suited for stylus-like writing of prototype devices using focused ion beams or for large-area writing of magnetic device architectures with a broad beam. The lithography and implantation tools necessary for these processes may already exist in the semiconductor foundries.

Ion-induced ferromagnetism in Fe\textsubscript{60}Al\textsubscript{40} has so far been studied on sheets of ∼100 µm thicknesses.\textsuperscript{21–23} At this thickness, incident ions cannot be made to fully penetrate the bulk-like material, ruling out the possibility of transport devices. Furthermore, the untransformed chemically ordered bulk material causes a large background signal, which interferes with the structural and magnetic property characterization of the disordered regions. In ref 21, the disordering effect of Ga\textsuperscript+ ions from a focused ion beam was used to write magnetic dots of ∼100 nm diameter at a separation of 500 nm; this large separation prevents any estimate of the ultimate patterning resolution. Here, a systematic study of the effect of chemical disorder on thin films of Fe\textsubscript{60}Al\textsubscript{40} with partial and full penetration by ions has been used to build a semiempirical model from which the effect of inhomogeneous depth penetration and lateral scattering of ions on the induced magnetization can be estimated.

While ion-irradiation is an attractive technique for the fabrication of devices, it can suffer from problems such as inhomogeneous depth penetration and lateral scattering. Because of these difficulties, previous literature does not unambiguously show that ion-irradiation can be used to fabricate discrete magnetic nanostructures at high resolution. In contrast, we present a method for achieving highly resolved magnetic structures and provide direct proof for their existence. We begin by showing the effect of chemical disordering on the ferromagnetic properties of thin Fe\textsubscript{60}Al\textsubscript{40} films.

**Chemical Disorder and Magnetic Properties.** In Fe\textsubscript{60}Al\textsubscript{40} alloys, the chemically ordered simple cubic B2 (CsCl) phase (space group 221) is paramagnetic whereas the disordered, body-centered cubic A2 phase (space group 229) is ferromagnetic.\textsuperscript{24–26} The structure of chemically ordered Fe–Al is schematically shown in Figure 1. The chemically ordered structure consists of planes of pure Fe separated by planes consisting of Al and the remaining Fe atoms. Each atom has 8 n-ns: the Fe atoms in the Al-rich planes have 8 n-ns of Fe and those in the pure-Fe planes have on average 1.6 Fe n-ns, making an average of 2.67 Fe–Fe n-ns in the chemically ordered structure. The Fe–Fe n-ns increase to 4.8 for the disordered structure where the Fe and Al atoms are randomly arranged. This increase in Fe–Fe n-ns is crucial for setting up exchange coupling and inducing ferromagnetism.\textsuperscript{27–30} Chemical disorder can be induced by ions possessing sufficient energy to knock Fe and Al atoms from their ordered sites. The vacancies formed in this process are filled with random occupancy due to thermal diffusion at room temperature, resulting in the B2→A2 phase transition.

The effect of ion-induced disorder is seen in the magnetic hysteresis loops of Figure 2a. Hysteresis loops were measured using a vibrating sample magnetometer (VSM) on Fe\textsubscript{60}Al\textsubscript{40} films of 40 nm nominal thickness, deposited on SiO\textsubscript{2}(150 nm)/Si(001) substrates. The films were annealed at 773 K in vacuum to induce chemical ordering. Figure 2a shows that the annealed sample is weakly ferromagnetic with a saturation magnetization of M\textsubscript{s} = 20 kA m\textsuperscript{-1}.

The chemically ordered samples were irradiated with 6 × 10\textsuperscript{15} ions cm\textsuperscript{-2} of N\textsubscript{2} ions at 10 and 30 keV respectively. According to simulations, ion-induced displacements of atoms follow a Gaussian-like distribution with the peaks located at

Figure 2. (a) Magnetic hysteresis loops for Fe₆₀Al₄₀ films of 40 nm thickness measured after vacuum annealing at 773 K (squares) and after irradiation of the annealed films with Ne⁺ at 10 keV (circles) and 30 keV (solid squares). A fluence of 6 × 10¹⁴ ions cm⁻² was used for the above irradiation exposures. (b) The 100 superstructure reflection obtained using X-ray diffraction for the sample after annealing and subsequent irradiation with Ne⁺ at 10 keV. (c) Cross-sectional high-resolution transmission electron microscopy image of the sample irradiated with 10 keV Ne⁺. (d) Selected area electron diffraction pattern of the Fe₆₀Al₄₀ film after annealing and (e) after 10 keV Ne⁺ irradiation. Concentric circles mark the 100 and 111 superstructure reflections (red) and 110 and 200 reflections (yellow). Arrows indicate the observed superstructure reflections.

Figure 3. (a) Optical micrograph of the Fe₆₀Al₄₀ wire of 10 μm width. (b) Scanning electron microscopy image of the wire surface with the resist mask. (c) Magnetic contrast obtained using Kerr microscopy showing the presence of ferromagnetic stripes. (d) Major hysteresis loop (circles) and partial hysteresis loops (lines) measured on a set of 32 pairs of magnetic stripes, with widths 0.5 μm and 2 μm respectively, formed due to chemical disorder induced by 10 keV Ne⁺ ions. The individual magnetic stripes are separated by weakly-magnetic regions of ~40 nm width. The spacers are formed due to the stopping of Ne⁺ ions by the resist mask shown in (b). (e–h) Magnetic contrast in the 10 μm wide wires corresponding to remnant points of the hysteresis loops shown in (d). Higher-resolution SPEEM images obtained after applying the same field history as in (d) are shown as magnifications of (e–g).
depths of 8.5 and 17 nm for Ne+ impinging at 10 and 30 keV, respectively.\textsuperscript{36} The effect of ion-induced disorder is clearly seen in the magnetic hysteresis, where $M_\text{sat}$ increases to 480 and 780 kA m$^{-1}$, respectively, for the 10 and 30 keV samples.\textsuperscript{37} The $M_\text{sat}$ of the 30 keV Ne+ sample is a factor of 40 larger than that of the annealed sample.

The magnetic behavior can be correlated to the chemical ordering. Figure 2b shows X-ray diffraction measurements around the 100 reflection for the sample after annealing and after subsequent 10 keV Ne+ irradiation. The 100 reflection is allowed for the B2 superstructure but vanishes for the disordered A2 phase. The annealed Fe$_{60}$Al$_{40}$ film possessing low $M_\text{sat}$ shows a clear superstructure reflection whereas this reflection vanishes for the 10 keV sample possessing higher $M_\text{sat}$.

A microscopic characterization of the film structure was obtained using cross-sectional high-resolution transmission electron microscopy (TEM). Figure 2c shows a TEM cross-section for the 10 keV sample. The actual Fe$_{60}$Al$_{40}$ thickness was close to 40 nm covered with a 4 nm thick continuous oxide layer. The well-defined substrate–film interface region suggests that possible intermixing with the SiO$_2$ buffer layer due to annealing and irradiation is negligible. The film surface was found to be smooth, pointing to negligible sputtering by the Ne+ ions. Selected area electron diffraction (SAED) patterns are shown in Figure 2d,e for the annealed and 10 keV Ne+ samples, respectively. In Figure 2d, the SAED pattern of the annealed sample matches that of B2 phase Fe$_{60}$Al$_{40}$.\textsuperscript{38} The superstructure reflections either vanish or are of lowered intensity on the 10 keV Ne+ irradiated sample (Figure 2e). The low intensity reflections suggest that some residual chemical order is retained despite exposure to 10 keV Ne+.

Thus ion-induced chemical disorder causes a significant increase of $M_\text{sat}$ in initially ordered Fe$_{60}$Al$_{40}$ thin films. Next, we attempt to localize the chemical disorder for fabricating magnetic structures into topographically flat films and to investigate the limits on the patterning resolution in the presence of lateral scattering of ions.

**Patterning of Reprogrammable Magnetic Structures.** Magnetic patterning was performed on a 10 μm wide and 400 μm long wire of chemically ordered Fe$_{60}$Al$_{40}$ (Figure 3a). The wire was covered with a 150 nm thick resist layer and patterned using e-beam lithography. TRIM simulation showed that the 150 nm thick resist layer is sufficient to block impinging 10 keV Ne+ ions.

Lithography was used to carve out stripe like openings of 0.5 and 2 μm widths. As shown in the micrograph in Figure 3b, the stripe-openings were separated by ≈40 nm wide (and 150 nm high) resist walls, thereby stopping the impinging Ne+ ions reaching the areas directly underneath the resist. These areas can be expected to retain chemical order after exposure to Ne+, however, only if the lateral scattering of ions is restricted. The wire covered by the shadow-mask was exposed to 10 keV Ne+ ions at a fluence of $6 \times 10^{14}$ ion cm$^{-2}$. Figure 3c shows the magnetic contrast image, obtained using Kerr Microscopy on the sample prior to application of saturating magnetic fields. Striped regions are clearly observed possessing random magnetic orientations.

Magnetic contrast was captured while sweeping the field to obtain hysteresis loops shown in Figure 3d on a set of 32 (0.5 μm/spacer/2 μm/spacer) stripe-pairs. Magnetic field, $B$, was applied perpendicular to the wire, that is, parallel to the 10 μm long edge of the ferromagnetic stripes. Magnetization reversal occurs via a two-staged process; the first reversal step occurs at $\sim$5 mT and the second step at $\sim$7 mT. The magneto-optic intensity changes by 80% in the first reversal step, indicating that the 2 μm wide stripes reverse collectively at the smaller field. In the stripe geometry, the internal demagnetizing field increases with the stripe width. Reversal of the 2 μm wide stripes therefore occurs at smaller externally applied field as compared with the 0.5 μm stripes, resulting in selective reversal.

To further test the selective reversal behavior, partial hysteresis loops were recorded, that is, the stripes were saturated in one direction at a field of $\pm$18 mT, subsequently the field was swept to a small reverse field of $\pm$5 mT and finally returned to $\pm$18 mT. As seen in Figure 3d, partial loops do not exhibit the second reversal stage, since after saturation the reversal fields for the 0.5 μm stripes were not reached; and the partial loops selectively reversed the 2 μm wide stripes. In the saturated state, the stripe magnetizations are aligned parallel, and after the first reversal step of the 2 μm wide stripes the stripe magnetizations are antiparallel (indicated by the arrows in Figure 3d).

Magnetic contrast images were captured at remnant points of the above hysteresis loops and are shown in Figure 3e–h. Stripes with magnetization pointing towards the left or right appear as dark and bright contrast, respectively. Images captured after applying the saturating field of $\pm$18 mT followed by reduction to zero field show that the parallel magnetization configuration is preserved in remanence (Figure 3e,f). The antiparallel configuration is obtained after applying a reverse field of $\pm$5 mT to the saturated stripes and returning to zero field. Figure 3g,h shows alternating light and dark contrast of the antiparallel state in remnant fields.

Thus, parallel and antiparallel magnetization configurations can be programmed using the magnetic field history and are nonvolatile, that is, stable when the field is switched off. Selective reversal and the existence of binary magnetic states viz., (↑↑), (↓↓), (↑↓), and (↓↑) is a prerequisite for spin-valves and advantageous in devices for storing data bits. In particular with respect to spin-transport devices, it is also necessary to ensure that the magnetic regions are separated by narrow spacers of zero or low magnetization. In order to prove the existence of the spacer, spin-resolved photo-emission electron microscopy (SPEEM) measurements that can achieve a spatial resolution below 50 nm were undertaken.

**X-ray Magnetic Imaging.** Magnetic contrast was obtained by illuminating the sample with circularly polarized X-rays at the energy corresponding to the Fe L$_3$ resonance. X-ray magnetic circular dichroism (XMCD), that is, the difference of two images taken with opposite helicity provides a measure of the magnetization component along the photon incidence direction. The direction of incidence was aligned parallel to the 10 μm long edge of the magnetic stripes.

The SPEEM micrographs are shown in Figure 3e,g as magnified equivalent regions of the Kerr-images. The color scale varies from red to blue for magnetic moments pointing left or right respectively. Straight, low-contrast regions are found to separate the 500 nm and 2 μm wide high-contrast regions that correspond to the magnetic stripes. Within the stripes, a substructure of meandering low-contrast regions are observed. These low-contrast regions (Figure 3e) tend to become broader at the wire-edge and narrower toward the center and are prominent only in the parallel configuration.
These regions nearly vanish in the antiparallel configuration, that is, they respond to the magnetic field. Therefore the meandering substructure likely corresponds to domains where the moments exhibit a large perpendicular component relative to the magnetic field, in order to minimize the stray field. The straight low-contrast regions, however, are unresponsive to the magnetic stripes, in order to minimize the stray field. Therefore the straight low-contrast lines also exactly follow the field and occur for both parallel and antiparallel states. Because the straight low-contrast lines also exactly follow the pattern of the shadow mask, it can be concluded that these lines correspond to the 40 nm wide unirradiated regions. Neighboring 500 nm and 2 μm wide ferromagnetic stripes are therefore isolated by a continuous weakly magnetic spacer of 40 nm nominal width.

Lateral scattering of ions however may penetrate the region underneath the 40 nm wide masks and further narrow the spacer regions. We attempt to estimate the extent of this effect through a semiempirical approach, and study its consequences on the patterning resolution.

**Semiempirical Modeling and Discussions.** The problem of estimating the magnetization induced due to the lateral scattering and inhomogeneous depth penetration of ions is approached by first relating the normalized increase of magnetization, $m$, to the average displacements undergone by an atom during the irradiation process, that is, displacements per atom (dpa). A B2→A2 transition occurring within a limited set of atoms with coexisting phases can be modeled by a sigmoidal function.

The above hypothesis can be tested by observing the dependence of $m$ on the fluence. A fluence gradient was obtained by making 20 keV Ne ions incident on the sample while blanking the ion-beam at a known rate using a mechanized shutter. In this way, the fluence was varied between 0 and $6 \times 10^{14}$ ions cm$^{-2}$. A polarized laser spot was scanned along the fluence gradient and the $m$ averaged over the probe depth, $(m)_x$, was measured using the magneto-optical Kerr effect (MOKE). Figure 4a shows a clear sigmoidal variation of $(m)$, the ion-fluence, and because fluence is proportional to dpa it confirms the validity of an s-shaped fitting curve.

The dpa caused by ions of a given energy can be calculated using the binary collision approximation. Simulations performed using the TRIM program reveal that Ne ions at 20 keV can cause ~320 displacements per ion, and the corresponding value for 5 and 10 keV are 98 and 185, respectively. The calculated spatial variation of dpa for Ne ions impinging on 40 nm thick Fe$_{60}$Al$_{40}$ films irradiated through a mask at energies of 5, 10, and 20 keV and fluence of $6 \times 10^{14}$ ions cm$^{-2}$ are shown in Figure 4b.

In the case of uniform irradiation, the dpa will remain constant in lateral position, $x$. The presence of a mask causes a variation of dpa in $x$. This was simulated by setting the mask edge at $x = 0$, such that no ions are incident for $x < 0$. Atomic displacements may still occur in regions where $x < 0$ purely due to lateral scattering. Moving away from the mask edge in the positive direction, dpa gradually increases finally reaching the constant value for uniform irradiation. As seen in Figure 4b, dpa varies in a quasi-Gaussian form with the film depth, $t$. The dpa($t$) at $x = +25$ nm is identical to that for a uniformly irradiated film.

Figure 4. (a) Variation of average magnetization $⟨m⟩$, with Ne$^+$ fluence at 20 keV, and (inset of a) $⟨m⟩$, variation with ion-energy at a fluence of $6 \times 10^{14}$ ions cm$^{-2}$. Red lines show the semiempirical data fitting. (b) Simulations showing the spatial distribution of the displacements per atom, dpa, in the vicinity of a mask, for Ne$^+$ at energies of 5, 10, and 20 keV and a fluence of $6 \times 10^{14}$ ions cm$^{-2}$. (c) Variation of induced magnetization $m$ with dpa, calculated from the semiempirical model. (d) Spatial-distribution of $m$ in the vicinity of a mask for the dpa-distributions shown in (b). (e) Projection of $m$ on the cross-sectional plane of the film for the 10 keV sample. The mask covers the lateral region between 0 and $-25$ nm, and $λ$ is the resolution of magnetic patterning.
The dpa(t) calculated for uniformly irradiated films will be used to fit the fluence variation shown in Figure 4a. An equation describing a sigmoid with m varying between 0 and 1 will be used to simulate the data; because the measurements are an average over the probe depth, it is necessary to integrate from the surface at $t = 0$, to the probe depth $t = t_f$ (ref 39)

$\langle m \rangle_f = \frac{1}{t_f} \int_0^{t_f} \frac{dpa(t)}{dp_0} \left( 1 + \frac{dpa(t)}{dp_0} \right)^{-1} dt$

(1)

where $dp_0$ is the dpa at which m equals 0.5 and $p = 2.3$, the semiempirical model fits the fluence-variation of $\langle m \rangle_f$ shown in Figure 4a. The sigmoidal $m(dpa)$ variation obtained by the above model is shown in Figure 4c.

The model can be cross-checked by fitting the variation of $\langle m \rangle_f$ with the ion-energy. The inset of Figure 4a shows that the same parameters also fit the variation of $\langle m \rangle_f$ with the ion-energy. Increasing the ion-energy results in deeper penetration of the ions and above a threshold the ions fully penetrate the film and maximum ($m_f$) can be achieved. Figure 4a shows that the given 40 nm thick Fe$_{60}$Al$_{40}$ films can be fully penetrated by 20 keV Ne$^+$-ions.

The semiempirical model can now be applied to the spatial distribution of dpa shown in Figure 4b, to obtain the spatial variation of $m$ in the vicinity of a mask-edge. The m-spatial distributions are shown in Figure 4d and reveal nearly discrete magnetic elements, where the depth and lateral penetration of the magnetized regions depends on the ion-energy. These plots can be used to estimate the lateral resolution of patterning, $\lambda$.

We define $\lambda$ as the minimum lateral spacing between two magnetic objects, while keeping $m < 0.001$ within the spacer region. Figure 4e shows the lateral projection of the m-spatial distribution for the 10 keV Ne$^+$ sample, with the projection of $m$ shown in color code and contour lines showing $m = 0.001$ to 0.99. It is seen that $m = 0.99$ is achieved directly underneath the mask edge and can be considered as the edge of the magnetic element. The lateral distance between the $m = 0.99$ and 0.001 contour lines then corresponds to $\lambda/2$. The conservative estimates of $\lambda$ for 5, 10, and 20 keV Ne$^+$ ions are 18, 31, and 47 nm respectively.

The 31 nm resolution calculated for 10 keV Ne$^+$ ions is consistent with the results in Figure 3 where separation between magnetic stripes was realized using an ~40 nm wide shadow mask. Varying the ion-energy provides depth control of the magnetic element. With 20 keV Ne$^+$ ions, full depth penetration and sub-50 nm patterning resolution can be achieved. Note that the lateral penetration of ions does not necessarily limit the patterning resolution and can indeed be exploited for patterning spacers that are narrower than the lithographed mask.

The present estimate of sub-50 nm patterning resolution is based on a semiempirical approach that considers the effect of lateral scattering of ions and has been confirmed through direct observation. Furthermore, the patterning resolution has been defined rather conservatively, requiring that the increase in magnetization at the center of the spacing between two magnetic objects is restricted to 1 part in 1000. A more conventional definition, analogous to photolithography, may require the magnetization increase at the spacing center to be restricted to half the maximum $M_s$ and as seen in Figure 4e the resolution in this case falls within the sub-10 nm range.

The high lateral patterning resolution originates from the sensitive dependence of the induced magnetization on the atomic displacements. The sensitive dependence seen in Figure 4c allows the tail regions of the quasi-Gaussian dpa variation to achieve maximum $M_s$, leading to the high definition of magnetic elements. The reason for the sensitivity of the phase transition to the ion-fluence lies in the fact that each ion can cause ~100 atomic displacements. Thus, a relatively small number of ions are sufficient to cause substantial changes to the local environment of the moment carrying Fe atoms.

A first approximation of the disorder induced variation in the Fe–Fe n-nm can be made by assuming 100% efficiency in recombination of vacancies (formed due to atomic displacements) with thermally diffusing atoms. In Figure 4c, it is seen that $m = 0.99$ is induced for $dpa = 0.5$. Assuming the probability of vacancy recombination with an Fe atom to be the same as the atomic fraction ($\sim0.6$), it can be seen that random displacement of half the atoms causes the Fe–Fe n-nm to increase to 3.6, thereby inducing 99% of the magnetization. This is consistent with reports, where the Fe–Fe n-nm were controlled by varying the composition of Fe–Al alloys and majority of the $M_s$ was induced as the Fe–Fe n-nm increased from 3 to 4.42 Furthermore, the magnetic moment per Fe-atom (estimated from Figure 2a) in the chemically ordered state is 0.04 $\mu_B$ and it increases to 1.67 $\mu_B$ for the disordered state, which is close to the 1.8 $\mu_B$ predicted from calculations.43 Ion-induced disorder in thin films could provide a way to directly observe the effect of purely varying the nearest neighbor interactions on, for instance, the spin and orbital contributions to the net magnetic moment, thereby shedding light on the mechanism of disorder induced ferromagnetism.

Conclusions. We show that sub-50 nm ion-induced lateral patterning of magnetic structures can be enabled by disorder-induced ferromagnetism, where the induced magnetization sensitively depends on the chemical disorder. Nearly discrete magnetic elements can be embedded within atomically flat films and can be made to partially or fully penetrate the film depth. The highly discrete magnetic resolution and the fine-tunability of magnetic properties may enable novel spin-transport and spin-wave devices. The semiempirical model shows that resolution can be sufficiently high such that the separation between the embedded magnetic objects can approach the spin-diffusion length of some materials, potentially making laterally patterned spin-transport devices viable. Ion-induced disorder can also provide a powerful way to modulate the $M_s$ of certain materials with nanoscale periodicity.44 Periodic magnetic structures may be fabricated using interference of femtosecond laser beams, to cause localized annealing of chemically disordered films at points of constructive interference.45 Showing that discrete magnetic nanostructures can be prepared using disorder induced ferromagnetism has important consequences not previously considered in literature, such as the possibility of laterally patterned spin-transport devices; our results are a step in this direction. These results may spur the search for new materials possessing disorder induced ferromagnetism for the local manipulation of magnetic properties.

Experimental charge exchange and energy loss data for the transmission of slow highly charged Xe ions through ultrathin polymeric carbon membranes are presented. Surprisingly, two distinct exit charge state distributions accompanied by charge exchange dependent energy losses are observed. The energy loss for ions exhibiting large charge loss shows a quadratic dependency on the incident charge state indicating that equilibrium stopping force values do not apply in this case. Additional angle resolved transmission measurements point on a significant contribution of elastic energy loss. The observations show that regimes of different impact parameters can be separated and thus a particle’s energy deposition in an ultrathin solid target may not be described in terms of an averaged energy loss per unit length.

DOI: 10.1103/PhysRevLett.112.153201 PACS numbers: 34.35.+a, 34.70.+e, 68.49.Sf, 79.20.Rf

Modern approaches in ion and electron irradiation of solids such as nano-structuring of thin films or even structuring of free-standing monolayers such as graphene [1–3] or MoS2 [4,5] rely on models for structural and electronic defect formation. Most important for processes during ion-solid interaction is the amount of deposited energy and its dissipation channels [6]. We show that the energy loss and charge exchange of ions in very thin films, such as two-dimensional materials, show significant differences to solids with reduced thickness. The understanding of these differences is not only of importance for ion beam analysis of two-dimensional materials but in particular for manipulating and tailoring their properties. [7]

To probe interaction processes in very thin target materials slow highly charged ions (HCI) are ideal tools due to their energy deposition confinement to shallow surface regions. Besides the well known near-surface potential energy deposition [8,9] also an expected increased preequilibrium kinetic energy loss (stopping force) [10] is confined to a few nm at the surface. In the conventional description of both contributions to the stopping force, i.e., nuclear and electronic stopping, the charge state of an ion is identified with its equilibrium charge state by Bohr’s stripping criterion [11,12]. The equilibrium charge state by Bohr is given as \( Q_{\text{eq}} = Z^{1/3} v_0 / v \) and describes the (average) charge state of an ion passing through a solid at a given velocity \( v \) (\( v_0 \): Bohr’s velocity, \( Z \): nuclear charge of the ion). The charge state \( Q \) of slow highly charged ions is much higher than the equilibrium charge state \( Q_{\text{eq}} \) (\( Q_{\text{eq}} \ll Q \ll Z \)). Therefore, the interaction of HCI with surfaces may not be described in terms of an equilibrium charge state dependent stopping force. Furthermore, due to the localization of the energy deposition slow HCl can be used as an efficient tool for surface nanostructuring [13–24] and tuning of the electrical properties of materials [25], as well as a probe for surface energy deposition processes [26,27].

Recently, it has been shown that slow HCI can create pores in 1 nm thick carbon nanomembranes (CNM) [28,29] mainly by deposition of their potential energy [30]. Here we report on measurements of kinetic energy loss and charge loss of slow highly charged Xe ions transmitted through 1 nm CNM. For carbon foils with larger thicknesses of 5 and 10 nm Schenkel et al. found evidence for a charge state dependent stopping force, whereas the total increase was reported to be small (factor 1.5) [31–33] for ions at about 2 keV/amu. This can be attributed to the fact that the equilibrium charge state is reached within the foil thickness and preequilibrium stopping force values may only contribute to a minor extent. In contrast, we observe two distinct exit charge state distributions with charge states much higher than the equilibrium charge state and an increase in stopping force with charge state by a factor up to 4, indicating that a 1 nm carbon layer is thin enough to address preequilibrium interaction processes of ions in solids. The two distributions allow a separation of different impact parameter regimes. This implicates that the interaction of particles with ultrathin solid targets may not be described in terms of an “average interaction per unit length.”

Highly charged ions are produced in a room-temperature electron beam ion trap [34] at the Ion Beam Center of the Helmholtz-Zentrum Dresden-Rossendorf. Xe ion charge states from \( Q = 10 – 30 \) are selected utilizing an analyzing magnet. To prevent charge exchange processes within the beam line or the experimental chamber the base pressure is kept below \( 5 \times 10^{-9} \) mbar for all experiments. The kinetic
ion energy is adjusted by means of an electrostatic deceleration system in the range of 40–135 keV (310–1050 eV/amu). Free-standing carbon nanomembranes with a thickness of 1 nm [28, 29] from CNM TECHNOLOGIES Bielefeld, Germany, on a standard transmission electron microscopy (TEM) grid with an underlying lacey carbon support are mounted within the experimental chamber. The membranes consist of a self-assembled monolayer of 1-1’-biphenyl-4-thiol (H-(C₆H₅)₂-SH), which has been cross-linked (polymerized) and hydrogen depleted by low-energy electron irradiation [28]. Contaminations of the CNM with light elements (O, F, I) have been reported [28] and additional sulfur contaminations are observed using Auger electron spectroscopy. The obtained concentrations are well below 1 at. % and are therefore neglected in the following discussion; i.e., the CNM is considered as pure carbon material. Possible hydrogen content of the CNM is assumed to be small due to hydrogen loss upon preparation of the CNM [29]. A separate manipulation stage within the experimental chamber holds an electrostatic analyzer with a HAMAMATSU PHOTONICS channeltron for ion counting. This manipulation stage allows angle resolved transmission measurements with an acceptance angle of the analyzer of 1.6°. The energy resolution of the analyzer is measured to be $\Delta E \approx 1.5 \times 10^{-3} E$, giving reasonable accuracy for charge exchange measurements. The total uncertainty in energy loss determination ranges from 60 to 200 eV mainly due to limited measurement precision, i.e., number of counted ions. Note that the mean energy of the transmitted ions is deduced from the median of the distribution of the corresponding exit charge state. The electrostatic energy filter allows 5000 V as maximum voltage, which leads to constraints in measurements of large charge exchanges. The primary ion beam is charge state analyzed without target by the electrostatic analyzer to check for charge exchange with residual gas atoms within the beam line. For incident ion charge states above $Q = 20$ ions are detected with a charge loss of $\Delta Q = Q_{\text{in}} - Q_{\text{exit}} = 1$ to 3. However, the amount of ions with lower charge states than the primary one is 4 orders of magnitude smaller. Their contribution can therefore be neglected.

The intensity of the ion beam is kept below 5000 ions/s with a typical beam diameter of 1.5 mm, yielding an ion flux of about $10^9$ cm$^{-2}$ h$^{-1}$. Significant damage of the membrane might occur only for exposure times longer than 100 h assuming a critical fluence of $10^{11}$ cm$^{-2}$, where 1% of the ions hit a previously damaged area of 10 nm$^2$. No degradation of the CNM during transmission measurements is observed.

TEM and helium ion microscopy studies of the CNM reveal that no pores larger than 1 nm in diameter exist. However, on a larger scale the membrane shows cracks (10–50 μm) due to a non-perfect coverage over large holes in the support film. Control experiments using a TEM grid with a lacey carbon support film but without a CNM showed no charge exchange nor energy loss. Thus, we can conclude that (a) ions penetrating the lacey carbon film are either stopped within the film or transmitted as neutral atoms and are therefore not detected and (b) that the amount of ions undergoing small angle deflections on the walls of supporting structure or during passage through cracks is negligible.

For slow highly charged Xe ions transmitted through a CNM, two distinct exit charge state distributions are observed. Figure 1 shows a typical transmission spectrum obtained with the electrostatic analyzer. The positions of the exit charge states are marked by arrows. The first distribution, ranging from $Q_{\text{exit}} = 29$ to 12, shows an intensity maximum at $Q_{\text{exit}} = 28$. Within the uncertainty of the measurement the peaks show no energy loss and no energy straggling. Note that the peak width originates from the channeltron entrance slit (detector resolution), whereas the uncertainty is determined by the steepness of the peak edges. The second distribution, ranging from $Q_{\text{exit}} = 12$ to 5, is instead combined with an energy loss and an energy straggling visible as a larger peak width in Fig. 1. Due to the voltage limitation of our spectrometer the maximum of the second distribution can not be determined.

In order to distinguish between possible processes leading to the two exit charge state distributions angle resolved transmission measurements are performed. Figure 2 depicts three different transmission spectra for a 46.8 keV Xe$^{28+}$ ion beam analyzed under 0°, 2°, and 4° projectile exit angle, respectively. Clearly the distribution of high charge states vanishes with tilting angle (see double logarithmic representation in the inset), while low charge states are transmitted up to 4°, even though the intensity decreases more than one order of magnitude. The energy losses $\Delta E(\alpha_{\text{exit}})$ for ions with $Q_{\text{exit}} = 2$ ($\Delta Q = 23$) are marked as well. From the increase in energy loss with deflection angle and the fact that the high charge state distribution is only observed in (exact) forward direction we conclude that the low charge state distribution results in a lower contribution to the overall transmission. This is consistent with the higher transmittance at 0° compared to 2° and 4°.

FIG. 1. (color online). Spectrum of a 1050 eV/amu Xe$^{30+}$ beam transmitted through a 1 nm thick carbon nanomembrane. All charge states below $Q = 30$ (but larger than $Q = 4$) are visible, whereas two distinct distributions can be observed. The high exit charge state distribution is magnified in the inset.
from close collisions of the ions with target atoms. Since the mass of Xe is approximately 10 times higher than the mass of C energy and momentum conservation yield a maximum deflection angle of 5.2° for one elastic scattering event. Due to the small thickness of 1 nm of the membrane we expect that the ions undergo at most one scattering event [35]. In contrast, the high exit charge state distribution is only observed under straight forward direction and the energy loss is negligible. This is attributed to the fact that for large impact parameters the deflection angle as a result of an elastic collision as well as the transferred energy (energy loss) become very small. In this case a contribution to the energy loss could only result from ion interaction with the electrons of the membrane. However, the observed energy loss for the high exit charge states is in any case smaller than the measurement uncertainty.

The measured energy loss at 0° for highly charged ions with a constant kinetic energy of 40 keV (310 eV/amu) but varying incident charge states is shown in Fig. 3, Figure 3(a) shows the mean energy loss as a function of the charge loss ΔQ. The energy loss is strongly dependent on the charge loss, whereas the same charge loss leads to different energy losses depending on the residual charge (e.g., ΔQ = 18 for Q_{in} = 20, 25, and 30, respectively [see Fig. 3(a)]). The green dots in Fig 3(b) represent the energy loss deduced from the peaks with ΔQ = 1, i.e., from ions which exhibit the smallest charge loss as a function of the incident charge state Q_{in}. The energy loss for these ions lies within the measurement uncertainty and can only be estimated to be smaller than 60 eV. The red dots in Fig. 3(b) show the energy loss obtained from the analysis of the Q_{exit} = 2 peaks, i.e., for ions with the highest charge loss observable with our setup. These ions show a quadratic increase of the mean energy loss with incident charge state [see fit in Fig 3(b)] and consequently a much higher value than predicted by TRIM [12]. In fact, the TRIM result of 237 eV reproduces the energy loss for a neutral atom (Q_{in} = 0) from an extrapolation of our measured data (ΔE(Q_{in}) = 3.7 eV · Q_{in}^2 + 264 eV). The dotted line shows the result from a TRIM simulation (see text).

To estimate the amount of ions transmitted at charge states, which can not be observed by the analyzer or even as neutrals, the transmission spectra have been normalized. For intensity normalization we employed the fact that a membrane usually does not cover the entire TEM grid perfectly but has some micrometer sized cracks. Ions which pass through these cracks do not interact with the target and therefore remain in their incident charge state without any
energy loss. For a constant incident kinetic ion energy of 40 keV the ratio of transmitted ions per exit charge state to the amount of transmitted ions through cracks is shown in Fig. 4. Note that all data shown in Fig. 4 are obtained from the same sample. The two distributions can clearly be distinguished by the minimum in between (e.g., $Q_{\text{exit}} = 11$ for $Q_{\text{in}} = 30$). Furthermore, the data indicate that for higher incident charge states more ions are neutralized. This can be derived from the steeper slopes towards lower exit charge states below the minimum for $Q_{\text{in}} = 30$ and 25 than for $Q_{\text{in}} = 20, 15, \text{and 10}$. This fact becomes more evident in Fig. 5 where the integral of the curves from Fig. 4 is plotted as a function of the incident charge state. An integrated normalized intensity of about 1–1.1 is obtained for incident charge states 10 to 20, whereas the value drops towards higher incident charge states to about 0.3. From the drop we conclude that for increasing incident charge states more ions are transmitted as single charged ions or as neutral atoms. Above a certain charge state the ion therefore captures electrons more effectively from the target system. The onset of the drop at about $Q_{\text{in}} = 20$ coincides very well with the observed potential energy threshold for preelectro production by HCl in CNI reported recently [30]. We conclude that the potential energy deposition becomes more efficient above a threshold charge state.

The fact that the two distributions are well separated may result from a strongly impact parameter dependent charge exchange. For close collisions, where also nuclear energy transfer occurs, the ion and the target atom (or target molecule) form a quasimolecule due to the strong overlap of their corresponding electronic wave functions. This overlap leads to a strong level shift [8] and therefore a direct capture of target electrons into inner shells of the ion. The consideration of the biphenyl molecule (or rather the aromatic ring after cross-linking) as the "target molecule" for the charge exchange process is physically justified by the delocalization of the carbon valence electrons over the aromatic ring and to some extend over its neighboring molecules. It also provides enough electrons to reach values of up to $\Delta Q = 28$. Contributions to the charge exchange from other species than carbon are neglected due to their small concentrations (< 1 at.%) and from hydrogen due to the fact that it provides only one electron per atom. For large impact parameters (> 2 Å) the nuclear charge of the carbon atoms is sufficiently screened and no nuclear energy transfer occurs. Electrons may only be transferred to the ion via classical over barrier transport [37,38], because no overlap of the electron densities of the molecule and the ion occurs. The critical distance $R_c \propto \sqrt{Q_{\text{in}} + \frac{2}{W}}$ for classical charge transfer depends on the work function $W$ of the material in the case of above surface neutralization [38]. The present experimental findings indicate a critical distance $R_c$ smaller than the interatomic distances in the membrane. Therefore the work function should be identified here with the ionization energy of the cross-linked biphenyl molecule or for simplicity with the atomic ionization energies (11, 24, 46 eV, ...) for successive ionization of carbon [39]. Since the second electron to be transferred has already a much higher binding energy than the first one, its exchange is only possible at much shorter distances. Niehaus showed in his extended classical over barrier model for charge exchange of highly charged ions interacting with molecules that the cross section for three-electron-capture is already about a factor of 30 smaller than the cross section for one-electron-capture [37]. Charge exchanges for impact parameter larger than those needed for a sufficient level shift are therefore limited to small $\Delta Q$. For slow highly charged ions interacting with very thin target materials the processes can hence be described better in a picture of ion-molecule interaction rather than ion-solid interaction. The concept of stopping force as the mean energy loss per unit length fails in a thin membrane, because no averaging over impact parameters appears anymore.

Induced by the combination of its magnetic and semiconducting properties below the Curie atomic percent of a magnetic element exhibit simultaneous magnetic and semiconducting properties below the Curie temperature. Large values of negative magnetoresistance and magnetic circular dichroism as well as an anomalous Hall effect are further evidence of a ferromagnetic order in InMnP. An effort is made to understand the transport mechanism in InMnP using the theoretical models. We find that the valence band of InP does not merge with the impurity band of the heavily doped ferromagnetic InMnP. Our results suggest that impurity band conduction is a characteristic of Mn-doped III-V semiconductors which have deep Mn-acceptor levels.

Diluted magnetic semiconductors (DMSs) containing a few atomic percent of a magnetic element exhibit simultaneous magnetic and semiconducting properties below the Curie temperature. The III-V based prototype ferromagnetic semiconductor GaMnAs has revealed a variety of unique features induced by the combination of its magnetic and semiconducting properties. Among these are the electric-field control of the Curie temperature and the magnetization direction and the low-current-density-induced magnetization reversal [3], which are expected to be useful for upcoming ultralow-power spintronic devices.

Yet controversy still surrounds the GaMnAs band structure and the mechanism behind the ferromagnetism. Generally two models are being used to explain the ferromagnetism in III-V semiconductors: the mean-field Zener model, where the ferromagnetism in III-V:Mn arises due to the $p-d$ exchange interaction between the valence band (VB) holes and the localized Mn-3$d$ electrons, and the Zener double-exchange model, where the hopping of the spin-polarized holes in the impurity band (IB) stabilizes the ferromagnetism. The former model seems to explain several features of GaMnAs, such as the carrier dependent metal-insulator transition [4], hole concentration dependent Curie temperature [5], etc. On the other hand, optical [6–8] and transport [9] studies of GaMnAs have revealed that the Fermi energy level ($E_F$) lies in the IB within the band gap of GaMnAs. Despite massive investigations on the origin and control of ferromagnetism in DMSs, the origin of ferromagnetism and the location of the impurity band in III-V-Mn semiconductors is still controversial [7,10–13]. Note that the Mn energy level ranges from 10 to 440 meV in different III-V hosts. It is unlikely that all different III-V-Mn combinations can be treated within a single model.

Scarpulla et al. prepared ferromagnetic GaMnP, which has the deepest Mn acceptor level (440 meV) among III-V semiconductors. They found that the ferromagnetic exchange coupling was mediated by holes localized in a Mn-derived band that is detached from the valence band [14]. Due to the deep Mn-acceptor level, strongly localized hole states are expected, leading to a detached impurity band in GaMnP. Moreover, GaMnP has an indirect band gap which also restricts its applications in optoelectronic devices. Therefore, it is worth choosing a system that has a band gap and Mn-acceptor energy level in between those of GaMnP (440 meV) and GaMnAs (110 meV) for a further understanding of the valence-impurity band dilemma in III-V semiconductors.

InP is a suitable candidate for investigating the existence and merging of the IB in InMnP, because it has a band gap (1.34 eV) closer to that of GaAs (1.42 eV) and a Mn-acceptor level at an energy 220 meV above the valence band which is almost half of the GaMnP [15]. Moreover, Dietl et al. have demonstrated theoretically that Mn-doped InP could be a promising diluted magnetic semiconductor (DMS) with a Curie temperature of $\sim 50$ K [16] where 5% Mn is substituted for the indium in the crystal grante nodes and is of $10^{20}$/cm$^3$ hole concentration. To the best of our knowledge, a comprehensive report on the magnetic properties of InMnP is lacking in the literature, except for some reports which, in our opinion, do not show clear evidence of carrier-mediated ferromagnetism in InMnP. First, undesirable secondary phases appear in samples annealed by conventional methods (e.g., thermal annealing) [17–19]. Second, ferromagnetism is reported in Zn-doped $p$-type InMnP for a Mn concentration of only 1 at. % [20]. This would be incompatible with the well-established theory of ferromagnetism in semiconductors [16,21]. There must be a sufficient amount of Mn ions (∼5 at. %) in the sample so that a net ferromagnetic order can be achieved at a reasonable high temperature (∼50 K). Hence, those previous reports neither prove the intrinsic mechanism of ferromagnetism nor do they give any insight into the nature of the impurity band in InMnP. Therefore, it is highly desirable to synthesize a diluted magnetic semiconductor, InMnP, with reliable magnetic and transport properties. It can also contribute to the understanding of the valence-impurity band picture in III-V semiconductors.

In this Rapid Communication we focus on the Mn-induced ferromagnetism and the location of the Mn-induced impurity band in InMnP prepared by Mn ion implantation and pulsed...
laser melting. We mainly discuss the results of a heavily doped (Mn 5 at. %) InMnP sample, however, some results of a low Mn-doped (Mn ∼ 2.5 at. %) InMnP sample are also included. The magnetization, magnetotransport, and x-ray magnetic circular dichroism (XMCD) measurements were carried out to support an intrinsic origin of ferromagnetism and the existence of a separate impurity band in InMnP.

Semi-insulating InP(100) wafers were implanted with 50 keV Mn+ to fluences of 2 × 10^{16}/cm^2 and 1 × 10^{17}/cm^2, hereafter referred to as sample A and sample B, respectively. After that the samples were annealed by an XeCl excimer laser using an energy density of 0.4 J/cm^2 for a single pulse duration (30 ns). The Mn concentration over a depth of around 90 nm (measured by transmission electron microscopy and Auger electron spectroscopy, not shown) for sample A was ∼5 at. %. Magnetization of the samples was measured by a superconducting quantum interference device (SQUID). Magnetotransport and XMCD measurements were performed using a Lakeshore system and at the beamline UE46/PGM-1 at BESSY II (Helmholtz-Zentrum Berlin), respectively.

Figure 1(a) shows the remanent magnetization versus temperature for three different InMnP samples. The Curie temperature (T_C) of the laser annealed samples A and B are found to be ∼42 and ∼20 K, respectively, while the as-implanted sample did not exhibit a ferromagnetically ordered state down to the lowest measured temperature. The inset of Fig. 1(a) represents the magnetic response of sample A as a function of a magnetic field at 5 K. There are two main contributions in the magnetic signals, a diamagnetic response which is due the InP substrate and a ferromagnetic one which originates from the Mn-implanted layer. It also shows a magnetic anisotropy (easy axis perpendicular to the sample plane) which often originates due to tensile strain, not only in Mn-implanted samples, but also in III-V semiconductors grown by molecular beam epitaxy (MBE) [22,23]. The dependence of Curie temperature on the Mn concentration supports the carrier-mediated ferromagnetism in InMnP.

Ferromagnetic loops are observed up to the Curie temperature for sample A, as shown in Fig. 1(b). The saturation magnetization at 5 K is ∼1.2 μ_B/Mn by considering that all implanted Mn ions contribute to the magnetization of the sample. Practically, this value is largely underestimated due to the following reasons: First, the sputtering effect in III-V semiconductors during ion implantation reduces the effective implantation fluence [24]. Second, it is known that the pulsed laser annealing results in a magnetically inert layer with a large Mn concentration due to surface segregation [25]. Moreover, self-compensation as in GaMnAs [26] can further depress the ferromagnetism in InMnP. If half of the implanted Mn concentration contributes to the total magnetization of InMnP, then the estimated magnetization will be ∼2.4 μ_B/Mn, which is comparable to the magnetization of InMnAs [22,27].

X-ray absorption spectroscopy (XAS) is widely used to probe the electronic structure of matter while x-ray magnetic circular dichroism (XMCD) by utilizing circularly polarized light gives selective elemental magnetic information about a specimen. We have performed XMCD measurements on sample A at the Mn L_{2,3} edges in which the 2p core electrons are excited to the unoccupied 3d states and consequently information about the electronic structure of the polarized Mn band is obtained (for more details, see Ref. [28] and references therein). The sample was etched in a diluted HCl solution (5%) prior to XMCD measurements to remove the surface oxide layer. This method has also been used previously for GaMnAs and GaMnP [29,30].

Figure 2(a) shows XAS spectra at the Mn L_{2,3} edges along with a XMCD spectrum in total electron yield (TEY) mode at 4.2 K under a magnetic field of 4 T for sample A. The main intense features in the XAS spectra at the L_{2,3} edges (at energies around 640 and 652 eV) are due to electric-dipole allowed transitions (i.e., Δε = ±1) from 2p to unfilled 3d states. A careful inspection of the XAS spectra of InMnP indicates that the spectral features are very similar to those of ferromagnetic GaMnP, GaMnAs, and InMnAs [25,29,30] regardless of whether they have different energy gaps and Mn-acceptor levels. It also hints to a similar bonding and p-d exchange interaction in most of the Mn-doped III-V semiconductors. The XMCD signal at the L_3 edge of InMnP defined as (μ^+ − μ^-)/(μ^+ + μ^-) is ∼40% at 4.2 K under a magnetic field of 4 T, which is comparable to that of ferromagnetic GaMnP [25]. The large XMCD signal of InMnP also indicates that it has a high spin polarization at the
Fermi energy ($E_f$). The XMCD sum rules also provide information on the degree of the spin and orbital moments in the system [31,32]. The spin moment calculated using XMCD data and the sum rules in InMnP sample A is $\sim 1\mu_B$/Mn while the orbital moment is negligibly small. This value of spin moment is slightly smaller than that obtained from SQUID measurements. The discrepancy in the magnetic moment could be due to the depth profile of the Mn concentration and the depth sensitivity of the two techniques (SQUID is volume sensitive while XMCD in the total electron yield mode is surface sensitive).

We have compared the magnetization measured by SQUID magnetometry and temperature dependent normalized XMCD signals in order to exclude any contribution from external impurities to the magnetization of the InMnP sample. Figure 2(b) shows the saturation magnetization and normalized XMCD signals of the same sample at different temperatures under a magnetic field of 0.5 T.

Another method for studying the carrier-mediated nature of ferromagnetism is the magnetotransport. We have carried out temperature dependent resistivity and magnetotransport (magnetoresistance, Hall effect) measurements on InMnP samples using van der Pauw geometry under a magnetic field perpendicular to the sample plane using a Lakeshore system. The temperature and magnetic field were varied up to 150 K and 6 T, respectively. Figure 3 shows the sheet resistance of InMnP samples A and B as a function of inverse temperature. The red solid lines show the fits of data to Eq. (1),

$$
\rho(T)^{-1} = [\rho_1 \exp(E_1/k_BT)]^{-1} + [\rho_2 \exp(E_2/k_BT)]^{-1},
$$

where preexponential constants $\rho_1, \rho_2$ and activation energies $E_1, E_2$ are the free parameters. The measured temperature dependent resistivity data fit to this model quite nicely. The fitting results indicate two thermally activated contributions to the resistivity of InMnP. For sample A a high temperature activation region with an activation energy $\sim 20$ meV ($E_1$) and a low temperature activation region with an energy $\sim 5.1$ meV ($E_2$) are observed. The activation energies in InMnP sample A for two activated regions are smaller than those of GaMnP [14], which are expected because of the following reason. The transition between the valence band and the acceptor states is responsible for the low resistivity at high temperatures. As the Mn-acceptor level in InMnP lies at a lower energy (220 meV) compared to GaMnP (400 meV), therefore, to excite an electron from the valence band to acceptor states needs less energy in InMnP. A close examination of the resistivity data of sample A in Fig. 3 also indicates a continuous change in the slope near $T_c$ (42 K), which can be due to the nearest-neighbor hopping transport [34] at low temperatures with an activation energy 5.1 meV in sample A. On the other hand, for the low Mn-doped InMnP sample B, $E_1$ and $E_2$ increase to $\sim 50$ and $\sim 18$ meV, respectively. This is expected due to the narrowing of the impurity band and the shift of...
the Fermi energy in the Mn-induced band accompanied by a reduction in hole concentration at a lower Mn concentration. It seems that, as least for semiconductors with deep Mn-acceptor levels, an impurity band is formed in heavily Mn-doped III-V semiconductors which is detached from the valence band. The high insulating character and the hopping transport in InMnP support a detached impurity band in InMnP.

To shed more light on the hopping transport mechanism in InMnP at low temperatures, we have performed magnetotransport experiments over a wider temperature range. Figure 4(a) shows the magnetoresistance of sample A measured at different temperatures above and below the Curie temperature. It exhibits negative magnetoresistance, as is typical for III-V diluted magnetic semiconductors. At the lowest measured temperature (15 K) the relative magnetoresistance, defined as $\text{MR(\%)} = \frac{\rho(H) - \rho(0)}{\rho(0)} \times 100$, is about 64% at 6 T, which increases with the temperature and reaches a maximum value of 66% at 20 K, and then decreases with the temperature. The negative magnetoresistance in InMnP can be explained as follows: When a magnetic field is applied, it results in an antiferromagnetic coupling between the Mn ion and the hole. Consequently, the wave functions of Mn-hole complexes expand and the increased overlapping of these wave functions results in a negative magnetoresistance of InMnP. We have used a model in high-field limits, i.e., $\lambda \ll a$, where $\lambda$ and $a$ are the magnetic length and localization radius, respectively, which has been previously used for insulating GaMnAs [35]. The model is given in Eq. (2),

$$\rho(H) = \rho_0 \exp \left[ \frac{C}{(\lambda^2 T)^{1/3}} \right].$$

where $\lambda = \left( \frac{\hbar}{e \mu B} \right)^{1/2}$ is the magnetic length. This model is used to fit the magnetoresistance data below $T_c$ and the results are shown in Fig. 4(b). The fit results show that the model is applicable to explain the magnetoresistance of InMnP in the high-field range of 1–6 T. The fitting parameter $C$ has a negative sign due to the expansion of the wave functions in a magnetic field. The magnetotransport results suggest that hopping is the main conduction mechanism in InMnP at low temperatures, which is also an indication of a separated Mn-impurity-induced band within the band gap of InP.

Finally, the anomalous Hall effect was measured in the InMnP sample. It reflects the presence of spin-polarized carriers along with their type and concentration in the sample. The Hall resistance $R_{\text{Hall}}$ of a magnetic semiconductor can be expressed phenomenologically as in Eq. (3),

$$R_{\text{Hall}} = R_0 B + R_s M.$$

The first term on the right-hand side of Eq. (3) is the ordinary Hall resistance while the second term stands for the anomalous Hall resistance. In general, the anomalous Hall contribution is proportional to the macroscopic magnetization of the sample [36]. Figure 5 shows the Hall resistance of InMnP sample A as a function of applied field measured at different temperatures. The Hall resistance of InMnP is dominated by the anomalous Hall component at low temperatures (see Fig. 5 and its inset). The temperature dependence and the shape of the Hall resistance is quite similar to that of magnetization of InMnP sample A. Therefore, we can conclude that both types of measurements reflect the intrinsic ferromagnetism of InMnP. The slope of the Hall resistance remains positive up to the measured temperatures and fields. This confirms that holes are the majority carriers in InMnP.

In conclusion, we have prepared the diluted magnetic semiconductor InMnP by Mn implantation and pulsed laser annealing. The transport results suggest that a separate impurity band formation is preferable even in heavily doped InMnP. The magnetization, x-ray circular dichroism, magnetoresistance, and anomalous Hall effect reflect an intrinsic ferromagnetic order in Mn-implanted InP A large XMCD signal and negative magnetoresistance indicate that InMnP has a high spin polarization at the Fermi energy ($E_F$) and the ferromagnetism is carrier mediated. Last but not least, a careful inspection of XAS spectra of InMnP points out that the spectral

FIG. 4. (Color online) (a) Magnetoresistance of an InMnP sample A measured at several temperatures. (b) The red solid lines show the fits of the data to a model given in Eq. (2). Note that for clarity, the MR curves measured at 20 and 30 K are shifted vertically by 3 and 9, respectively.

FIG. 5. (Color online) Anomalous Hall effect in InMnP at different temperatures. The inset shows the anomalous Hall effect below $T_c$. The temperature dependence and the shape of the Hall resistance is quite similar to that of magnetization of InMnP sample A. Therefore, we can conclude that both types of measurements reflect the intrinsic ferromagnetism of InMnP. The slope of the Hall resistance remains positive up to the measured temperatures and fields. This confirms that holes are the majority carriers in InMnP.
features are very similar to those of ferromagnetic GaMnP and GaMnAs [14] regardless of whether they have different energy gaps and Mn-acceptor levels. The high insulating character of InMnP is very similar to that of GaMnP, which could be due to strong localization of carriers in an impurity band (low mobility) and the hopping transport mechanism supports a separate impurity band formation in InMnP and similar III-V semiconductors which have deep Mn-acceptor levels.

The authors thank René Hübner for transmission electron microscopy measurements. The work is financially supported by the Helmholtz-Gemeinschaft Deutscher Forschungszentren (VH-NG-713).

BSc theses

1. Hoffmann, S.
   Magnetische Charakterisierung dünner Keilschichten mittels frequenzaufgelöstem
   magnetooptischen Kerr-Effekt
   TU Ilmenau, 16.12.2014

2. Liersch, V.
   Herstellung und Charakterisierung eines Spinventils zur Untersuchung der
   Spindiffusionslänge von FeAl
   Westsächsische Hochschule Zwickau, 21.03.2014

3. Rupp, S.
   Untersuchung der magnetischen Eigenschaften von Permalloy-Filmen mittels
   frequenzaufgelöstem magnetooptischen Kerr-Effekt (FR-MOKE)
   nta Naturwissenschaftlich-Technische Akademie Prof. Dr. Grübler gGmbH, 27.02.2014
Appointments and honors

Appointments

1. **Ou, Xin**
Scientist in the research group “Ion Induced Nanostructures” of the Ion Beam Center has received a **professorship** within **The Hundred Talents Program** of the Chinese Academy of Sciences (CAS).

Awards and honors

1. **Bogusz, Agnieszka**
PhD candidate in the Virtual Institute (VI) MEMRIOX and the division “Semiconductor Materials” won an **Excellent Student Paper Certificate** at the 12th International Conference on Solid-State and Integrated Circuit Technology (ICSICT), 28-31 Oct 2014, Guilin, China.

2. **Bogusz, Agnieszka**

3. **Facsko, Stefan; Heller, René; Wilhelm, Richard**
Members of the research group “Ion Induced Nanostructures” at the Ion Beam Center received the **HZDR Research Award 2014** for their investigations of slow highly charged ions interacting with carbon nano membranes and surfaces of ionic crystals.

4. **Gao, Kun**

5. **Gao, Kun**
PhD candidate in the Helmholtz Young Investigator Group “Functional Materials” of the division “Semiconductor Materials” received the **Best Poster Prize**: “Ge_{0.1x} Sn_{0.9} alloy synthesized by ion-implantation: from epitaxial thin films to crystalline nanostructures” at the international conference "Trends in Nanotechnology 2014", 27-31 Oct 2014, Barcelona, Spain.

6. **Kolitsch, Andreas**
Senior Scientist at the Ion Beam Center was appointed as **Guest professor** at the Faculty of materials science of the Slovak University of Technology Bratislava for a period of two years.

7. **Mittendorff, Martin**
Scientist in the “Spectroscopy” division received a **HZDR Ph.D. Recognition Award 2014** for his thesis on “Carrier Relaxation Dynamics in Graphene”.

8. **Prucnal, Slawomir**

9. **Schneider, Harald**
Head of the “Spectroscopy” division was selected for the **Chinese National 1000 Foreign Experts Program** but declined a professorship at the Shanghai Jiao Tong University in Shanghai, China.
10. **Schultheiß, Helmut**  
PostDoc in the “Magnetism” division received funding of the Emmy-Noether-Young-Investigator-Group “Magnonics: Spin waves bridging Spintronics and Photonics” by the Deutsche Forschungsgemeinschaft (DFG).

11. **Schultheiß, Helmut**  
PostDoc in the “Magnetism” division was elected as Member of the Editorial Review Board of the journal “IEEE Magnetics Letters”.

12. **Winnerl, Stephan**  
PostDoc in the “Spectroscopy” division was elected as HZDR Research Fellow for his outstanding internationally renowned scientific achievements in the field of terahertz and ultrafast spectroscopy.
Invited conference contributions, colloquia, lectures and talks

Invited conference talks

   High-Speed PIXE: Fast multi-elemental analysis with lateral resolution using a Colour X-Ray Camera
   8th International Symposium on BioPIXE, 15.-19.09.2014, Bled, Slovenia

   High-Speed PIXE: Fast Elemental Analysis with a Colour X-Ray Camera
   14th International Conference on Nuclear Microprobe Technology and Applications, 06.-11.07.2014, Padova, Italy

3. Facsko, S.; Ou, X.
   Spontaneous pattern formation in reverse epitaxy
   5th International Conference on NANO-structures SElf-Assembly, 07.-11.07.2014, Marseille, France

   Faceting semiconductor surfaces by reverse epitaxy
   16th International Conference on Thin Films, 13.-16.10.2014, Dubrovnik, Croatia

5. Fassbender, J.
   Magnetic films tailored by ion irradiation
   Physics of Surfaces and Interfaces, 24.-28.02.2014, Puri, India

   Self-organized Nanopatterns on Silicon Surfaces by Ion-Beam-Sputtering with Metal Co-deposition
   2014 MRS Spring Meeting, 21.-25.04.2014, San Francisco, USA

   The interaction of slow highly charged ions with carbon nano membranes
   20th International Workshop on Inelastic Ion-Surface Collisions (IISC-20), 16.-21.02.2014, Adelaide, Australia

   Population dynamics in graphene Landau levels
   International Quantum Cascade Lasers School and Workshop 2014, 07.-12.09.2014, Policoro, Italy

   Atomistic modeling of ion-beam induced processes in Si and Ge
   Swift Heavy ions in Materials Engineering and Characterization (SHIMEC 2014), 14.-17.10.2014, New Delhi, India

10. Möller, W.
    Ion-surface interaction in plasma processing

    Reverse Epitaxy on Semiconductor Surfaces
    The 10th international ESPS-NIS workshop, 20.-23.07.2014, Traunkirchen, Austria
Reverse epitaxy on Ge surfaces
23rd Conference on Application of Accelerators in Research and Industry, 25.-30.05.2014, San Antonio, USA

Hyperdoping of semiconductors by ion implantation and ultrafast annealing: solid vs. liquid phase epitaxy
ION 2014 - X-th International Conference on Ion Implantation and Other Applications of Ions and Electrons, 23.-26.06.2014, Kazimierz Dolny, Poland

Rare Earth Doped Metal-Oxide-Semiconductor Structures: A Promising Material System or a Dead End of Optoelectronic Evolution?
225th ECS Meeting, 11.-15.05.2014, Orlando, USA

Geometallurgy of REE deposits - state of the art
Geology to Metallurgy of Critical Rare Earths, 24.-25.03.2014, Penryn, UK

Progress at DRESden AMS
DPG-Frühjahrstagung der Sektion AMOP (SAMOP), 17.-21.03.2014, Berlin, Germany

17. Schneider, H.
QWIP-Based “Ultrafast” Detectors for QCL Research

18. Schneider, H.
Coherent and nonlinear terahertz spectroscopy of low-dimensional semiconductors with a free-electron laser
7th International Symposium on Ultrafast Phenomena and Terahertz Waves (ISUPTW 2014), 13.-14.10.2014, Shanghai, China

19. Skorupa, W.
Quo vadis?: Ion Beam Engineering and beyond...
X-th International Conference Ion Implantation and other Applications of Ions and Electrons, 23.-26.06.2014, Kazimierz Dolny, Poland

Realization of a spin-wave multiplexer
59th Annual Magnetism & Magnetic Materials Conference, 03.-7.11.2014, Honolulu, USA

Advanced ms-annealing concepts for semiconducting oxides for PV applications
E-MRS Fall Meeting 2014, 15.-18.09.2014, Warszawa, Poland

Interaction of Slow Highly Charged Ions with Ultrathin Membranes
17th International Conference Physics of Highly Charged Ions (HCI2014), 31.08.-05.09.2014, San Carlos de Bariloche, Argentina

23. Winnerl, S.; Mittendorff, M.; Teich, M.; Jacob, R.; Schneider, H.; Helm, M.
Kurzzeit-Spektroskopie an Halbleiter-Quantenstrukturen am Freie-Elektronen-Laser FELBE
Deutsche Tagung für Forschung mit Synchrotronstrahlung, Neutronen und Ionenstrahlen an Großgeräten 2014 (SNI 2014), 21.-23.09.2014, Bonn, Germany

24. Winnerl, S.; Mittendorff, M.; Wendler, F.; Malic, E.; Knorr, A.; Schneider, H.; Helm, M.
Ultrafast spectroscopy on Landau quantized graphene: Evidence for strong Auger scattering
5th International Symposium on Terahertz Nanoscience, 01.-05.12.2014, Schoelcher, Martinique, France

25. Wintz, S. 
Topology and Origin of Effective Spin Meron Pairs in Ferromagnetic Multilayer Elements 
DPG-Frühjahrstagung der Sektion Kondensierte Materie, 30.03.-04.04.2014, Dresden, Germany

26. Wintz, S.; Raabe, J.; Fassbender, J. 
Effective spin meron pairs in ferromagnetic multilayer elements 
59th Annual Magnetism & Magnetic Materials Conference, 03.-07.11.2014, Honolulu, USA

27. Yankov, R.; Borany, J. von; Masset, P. J.; Donchev, A.; Schütze, M. 
Recent developments in surface protection of titanium and titanium-aluminum alloys against environmental degradation at elevated temperatures 
Shechtman International Symposium, 29.06.-04.07.2014, Cancun, Mexico

28. Zhou, S. 
Ion beam synthesis of the full spectrum of III-V:Mn ferromagnetic semiconductors 
E-MRS 2014 SPRING MEETING, 26.-30.05.2014, Lille, France

29. Zhou, S. 
Ion beam synthesis of the full spectrum of III-V:Mn ferromagnetic semiconductors 
X-th International Conference - Ion Implantation and Other Applications of Ions and Electrons, 23.-26.06.2014, Kazimierz Dolny, Poland

30. Zhou, S. 
Ion beam synthesis of the full spectrum of III-V:Mn ferromagnetic semiconductors 
The Moscow International Symposium on Magnetism 2014, 29.06.-03.07.2014, Moscow, Russia

Colloquia

31. Fassbender, J. 
Nanomagnets - created and tailored by ions 
Colloquium, Institute of Physics, 21.02.2014, Bhubaneswar, India

32. Fassbender, J. 
Nanomagnets - created and tailored by ions 
Kolloquium, Universität Kiel, 27.01.2014, Kiel, Germany

33. Fassbender, J. 
Nanomagnets - created and tailored by ions 
Colloquium, Institute of Physics, Polish Academy of Sciences, 07.10.2014, Warschau, Poland

34. Fassbender, J. 
Form follows function - neue Funktionalitäten durch Nanostrukturierung 
10 Jahre Nano Structuring Centre Kaiserslautern, 08.07.2014, Kaiserslautern, Germany

35. Gensch, M. 
Long waves from short bunches: Concepts and applications of super-radiant THz sources 
Kolloquium der Fakultät für Physik, KIT, 31.01.2014, Karlsruhe, Germany

36. Gensch, M. 
THz driven Dynamics in Matter: Sources and Applications 
Kolloquium des Instituts für Analytische Wissenschaften (ISAS), 17.11.2014, Berlin, Germany

37. Hlawacek, G. 
The dark side of Helium Ion Microscopy 
Kolloquium, 06.06.2014, Bielefeld, Germany

38. Hlawacek, G. 
5 years of Helium Ion Microscopy 
Kolloquium PIN/UTwente, 17.04.2014, Enschede, Netherlands

39. Hübner, R. 
Transmission Electron Microscopy at the Helmholtz-Zentrum Dresden-Rossendorf (HZDR) 
Kolloquium des Instituts für Strukturphysik der TU Dresden, 28.01.2014, Dresden, Germany
Lectures and talks

   *Printing Nearly-Discrete Magnetic Patterns using Chemical Disorder Induced Ferromagnetism*
   *Sixth Joint BER II and BESSY II User Meeting, 03.-05.12.2014, Berlin, Germany*

   *High-Speed PIXE: A spatially resolved PIXE setup at the 6 MV Tandem accelerator*
   *SLcam© User Workshop, 16.01.2014, Berlin, Germany*

42. Cornelius, S.
   *Dopant activation and charge transport limits in transparent conductive (Al,Ga):ZnO and Nb:TiO2*
   *Institutsseminar, Institut für experimentelle Physik II, Universität Leipzig, 26.11.2014, Leipzig, Germany*

43. Devaraj, M.
   *Properties of oxide nanoclusters in ODS ferritic steels: A combined DFT and Monte Carlo simulation study*
   *Seminar talk Department of Mathematical Sciences, Loughborough University, 02.10.2014, Loughborough, UK*

44. Erbe, A.
   *Transport in mesoscopic conductors*
   *PIER summer school, 06.-09.10.2014, Hamburg, Germany*

45. Erbe, A.
   *Introduction to transport in confined geometries and across point contacts*
   *MAINZ summer school, 25.-29.08.2014, Mainz, Germany*

46. Erbe, A.; Gemming, S.
   *Nanoscale Transport Phenomena*
   *Abengoa Research Seminar, 20.05.2014, Sevilla, Spain*

47. Facsko, S.
   *Vacancy controlled spontaneous pattern formation on semiconductor surfaces*
   *Seminar, 12.11.2014, Stuttgart, Germany*

48. Facsko, S.
   *Low energy ion irradiations in material research*
   *Seminar, 20.06.2014, Cork, Ireland*

   *Energy Loss and Charge Exchange of Highly Charged Ions in Carbon Nanomembranes*
   *Seminar an der Fakultät für Physik der Universität Bielefeld, 06.06.2014, Bielefeld, Germany*

50. Gemming, S.
   *Kleinste Strukturen ganz groß – Forschung mit Großgeräten*
   *Seniorenkolleg der TU Chemnitz, 27.05.2014, Chemnitz, Germany*

51. Gensch, M.
   *High field THz sources operating at 100 kHz Repetition rates: Challenges and Opportunities*
   *Seminar of the Stanford Institute for Materials and Energy Sciences, 12.09.2014, Stanford / SLAC, USA*

   *Transport in Nanoelectronic Systems*
   *9th Silicon Saxony Day, 03.07.2014, Dresden, Germany*
53. Grenzer, J.  
**X-ray Diffraction and Scattering from Nanostructures**  
*Workshop on X-ray Scattering Methods for Thin Film Characterization, 25.-26.09.2014, Prague, Czech Republic*

54. Grenzer, J.  
**In-situ X-ray experiments for material science**  
*Workshop „Advanced X-ray Diffraction for Semiconductor Materials and Technology“, 03.-04.04.2014, Frankfurt/Oder, Germany*

55. Günther, F.; Gemming, S.; Seifert, G.  
**Calculation of Electronic Structure and Transport properties of Donor – Acceptor Polymers**  
*Seminar der Professur Theorie ungeordneter Systeme TU Chemnitz, 17.12.2014, Chemnitz, Germany*

56. Günther, F.; Gemming, S.; Seifert, G.  
**Calculation of Electronic Structure and Transport properties of Donor – Acceptor Polymers**  
*Arbeitsgruppenseminar der Professur für Theoretische Chemie TU Dresden, 20.11.2014, Dresden, Germany*

57. Helm, M.  
**THz spectroscopy of solids using a free-electron laser**  
*Seminarvortrag am Fritz-Haber-Institut (FHI) Berlin, 20.10.2014, Berlin, Germany*

58. Helm, M.  
**Terahertz spectroscopy of nanostructures with a free electron laser**  
*Annual BuildMoNa Conference, 04.03.2014, Leipzig, Germany*

59. Hlawacek, G.  
**The He ion microscope - a high resolution tool for the nano–world**  
*ANP retreat, 19.-20.06.2014, Tecklenburg, Germany*

60. Hlawacek, G.; Veligura, V.; Bali, R.; van Gastel, R.; Poelsema, B.; Facsko, S.  
**Helium Ion Microscopy: A high resolution tool for the nano-world**  
*Workshop Ionenstrahlen & Nanostrukturen, 20.-22.07.2014, Paderborn, Germany*

61. Krause, M.  
**The Ion Beam Center at the HZDR, nanocomposite growth with ions, and cluster tool setting up**  
*Seminar at Abengoa Research, 12.02.2014, Seville, Spain*

**Evolution of Spin Wave Modes in Periodically Perturbed Thin Films**  
*Gruppenseminar der AG Küpper an der TU Osnabrück, 10.-11.12.2014, Osnabrück, Germany*

63. Liedke, B.  
**Power of the sun is all we need for a power plant**  
*Science slam in Köln, 07.11.2014, Köln, Germany*

**Sponge-like Si-SiO₂ nanocomposite for PV applications**  
*Seminar an der TU Bergakademie Freiberg, 15.07.2014, Freiberg, Germany*

**Atomistic modeling of ion-beam and thermally induced processes in Si and Ge**  
*Seminar at the KTH Royal Institute of Technology - Reactor Physics, 12.11.2014, Stockholm, Sweden*

66. Mittendorff, M.  
**Kurzzeitpektroskopie: Kürzeste Laserpulse für Materialuntersuchungen**  
*2. Fortbildungsveranstaltung zu Optotechnik und Bildverarbeitung, 27.06.2014, Darmstadt, Germany*
67. Pelic, B.; Skorupa, W.
Plasma-based nanotechnology against corrosion of organ pipes
Final conference of the EU research project “EU-PANNA”, 04.09.2014, Berlin, Germany

68. Schmidt, H.; Wiesenhütter, K.; Teichmann, D.
PolCarr - Smart Trägermaterialien für die Biotechnologie
Cross Cluster Cooperation-Projekt „C3-Saxony“, IDEA CALL zum 9. Silicon Saxony Day, 03.07.2014, Dresden, Germany

69. Schneider, H.
High-performance QWIPs and time-resolved terahertz spectroscopy with a free-electron laser
Seminar, Kunming Institute of Physics, 17.10.2014, Kunming, China

70. Schneider, H.
Quantum structure THz photonics and spectroscopy at HZDR
Seminarvortrag, Centre Suisse d’Electronique et Microtechnique SA (CSEM), 19.09.2014, Neuchâtel, Switzerland

71. Schneider, T.; Hübner, R.; Lenz, K.; Lindner, J.; Fassbender, J.
Investigation of interlayer exchange coupling and magnetic anisotropy of Fe3Si-trilayers using ferromagnetic resonance
Gruppenseminar AG Wende, 14.01.2014, Duisburg, Germany

72. Wiesenhütter, K.; Urban, B.; Müller, M.; Müller, A.-D.; Skorupa, I.; Rüb, M.; Skorupa, W.; Schmidt, O. G.; Schmidt, H.
PolCarr: Smart carriers for advanced manufacturing in biotechnology
Bionection Partnering Conference for Technology Transfer in Life Sciences, 09.-10.10.2014, Dresden, Germany

73. Wiesenhütter, K.; Urban, B.; Müller, M.; Müller, A.-D.; Skorupa, I.; Rüb, M.; Skorupa, W.; Schmidt, O. G.; Schmidt, H.
PolCarr® - Smart carriers for advanced manufacturing in biotechnology
Conferences, workshops, colloquia and seminars

Organization of conferences and workshops

1. Altstadt, E.; Colomer, M.
   **LONGLIFE Final Workshop**
   15. - 16.01.2014, Dresden, Germany

2. Bergner, F.; Heintze, C.; Hilger, I.; Posselt, M.
   **2nd International Workshop on ODS Materials**
   26. - 27.06.2014, Dresden, Germany

3. Blom, P.; Kläui, M.; Erbe, A.
   **Summer School: Charge and Spin Transport in Non-Metallic Systems and Confined Geometries**
   24. - 29.08.2014, Mainz, Germany

4. Erbe, A.; Zahn, P.
   **IHRS NanoNet Annual Workshop 2014**
   29. - 30.09.2014, Lohmen, Germany

Colloquia

1. Berger, Andreas
   CIC nanoGUNE Consolider, Donostia, Spain
   **Focused Electron Beam Induced Deposition (FEBID) fabrication of nano-magnets and their magneto-optical characterization**
   11.07.2014

2. Celinski, Zbigniew
   University of Colorado, Physics Department, Colorado Springs
   **On-wafer microwave materials and devices**
   23.01.2014

3. Celler, George
   Rutgers University, Piscataway, NJ, USA
   **Laser annealing of semiconductors, what we learned 35 years ago, and why it still matters today**
   27.06.2014

4. Coker, Jonathan
   HGST, a Western Digital Company, San Jose, CA, USA
   **Opportunities and challenges in two dimensional magnetic recording**
   09.04.2014

5. Feng, Xinliang
   TU Dresden, Department of Chemistry and Food Chemistry
   **A milestone of Graphene Chemistry: From controlled synthesis to electronics and energy technologies**
   20.11.2014

6. Hjörvarsson, Björgvin
   Uppsala University, Department of Physics and Astronomy, Sweden
   **Demystifying nano - The influence of confinement and strain on hydrogen uptake**
   22.05.2014

7. Kent, Andrew
   New York University, Department of Physics, NY, USA
   **Current-induced torques in magnetic materials**
   09.05.2014
8. Kläui, Mathias  
Johannes-Gutenberg-Universität Mainz, Institut für Physik  
Ultra-fast domain wall dynamics  
05.06.2014
9. Leyens, Christoph  
TU Dresden/Institut für Werkstoffwissenschaft und Fraunhofer IWS/Abteilung Thermisches Beschichten und Generieren  
Entwicklungen von Schutzschichten und Reparaturverfahren für Luftfahrtauteile  
30.04.2014
10. Mayr, Stefan G.  
IOM Leipzig  
Ferromagnetic shape memory alloys: From ion beam assisted synthesis to plasma-assisted functionalization for biomedical applications  
23.10.2014
11. Riel, Heike  
IBM Research Zürich, Switzerland  
Semiconducting nanowires – From materials to devices  
27.03.2014
12. Sawicki, Maciek  
Institute of Physics, Polish Academy of Science, Warsaw, Poland  
The Origin of Ferromagnetism and Critical Behavior in Insulating (Ga,Mn)N  
18.11.2014

Seminars
1. Bakaev, Alexander  
SCK-CEN, Nuclear Materials Science Institute, Mol, Belgium  
Segregation-induced embrittlement in RPV steels; assessment by atomistic simulations  
14.08.2014
2. Bedanta, Subhankar  
School of Physics, National Institute of Science Education and Research (NISER), IOP Campus, Bhubaneswar, India  
Supermagnetism - State-of-art and challenges ahead  
17.02.2014
3. Boucher, Richard  
Leibniz-Institut für Festkörper- und Werkstoffforschung Dresden  
Influence of a Plasma Surface Treatment on the Electrical Properties of Bulk PZT  
31.01.2014
4. Bourlès, Didier L.  
CEREGE, CNRS, Aix-en-Provence, France  
Dating fossiliferous deposits and archaeological sites: a new accelerator mass spectrometry perspective  
08.12.2014
5. Braun, Johannes  
Universität Konstanz  
High-power Thulium-doped fiber amplifier  
06.05.2014
6. Celler, George  
Rutgers University, Piscataway, NJ, USA  
Properties of H+ implanted 4H-SiC as related to exfoliation of thin crystalline films  
27.06.2014
7. Chernykh, Pavel  
Division of the atomic nuclear physics (DANP), Lomonosov Moscow State University, Skobeltsyn Institute of Nuclear Physics (MSU SINP), Russia  
*Ion-beam techniques for research and modification on coatings*  
07.01.2014

8. Dev, Bhupeendra  
Indian Association for the Cultivation of Science, Kolkata, India  
*Epitaxial nanostructures on surfaces: The role of surface symmetry and nanodot to nanowire shape transition*  
07.07.2014

9. Ebke, Daniel  
Max-Planck-Institute for Chemical Physics of the Solids, Dresden  
*New Heusler compounds for spintronic applications*  
30.01.2014

10. Ehrler, Jonathan  
TU Dresden  
*Improved crack propagation analysis with increased spatial resolution in the structure of microprocessors*  
19.09.2014

11. Engler, Martin  
Institute of Physics II, University of Cologne  
*Self-organized ion induced pattern formation on Si(001)*  
24.11.2014

12. Forstner, Oliver  
VERA Laboratory, Faculty of Physics, University of Vienna, Austria  
*Laser-Photodetachment of negative ions: Possible solution to the isobar problem in AMS?*  
07.04.2014

13. Fuchs, Florian  
TU Chemnitz  
*Simulating electronic transport through carbon nanotubes and related nanostructures*  
15.10.2014

14. Galindo, Ramón Escobar  
Abengoa Research, Sevilla, Spain  
*Absorber Layers for concentrated Solar Power*  
23.09.2014

15. Gonzalez-Elipe, Augustín R.  
Materials Science Institute of Seville, Spain  
*Enhanced porosity in oxide thin films and nanostructures prepared by vacuum and plasma procedures: synthesis, modeling and applications*  
28.04.2014

16. Güttler, Dominik  
ETH Zürich, Switzerland  
*Super-SIMS and C-14 AMS in Zurich: Challenges and applications*  
18.12.2014

17. Hoekstra, Ronnie  
University of Groningen, The Netherlands  
*Unravelling the Different Potential Energy Contributions to the Secondary Electron Yields of Highly Charged Ar and Xe Ions Impacting on HOPG*  
21.10.2014

18. Jamshidi, Kambiz  
TU Dresden, Faculty of Electrical and Computer Engineering, Communications Lab  
*Integrated photonic devices for communications and signal processing*  
29.10.2014
19. Josten, Elisabeth  
FZ Jülich  
**Long range order in 3D nanoparticle assemblies**  
12.09.2014

20. Keleş, Ümit  
Bilkent University, Ankara, Turkey  
**Silicon Nanowire-based Complex Structures: a large-scale atomistic electronic structure and ballistic transport**  
04.11.2014

21. Knyazev, Boris  
Budker Institute of Nuclear Physics SB RAS and Novosibirsk State University, Novosibirsk, Russia  
**Ten years of operation of Novosibirsk free electron laser: status of the facility and recent experimental results**  
28.11.2014

22. König, Dirk  
Theory and Characterization Group, 3rd Generation Dept., Australian Centre for Advanced Photovoltaics, Sydney, Australia  
**Alternatives to Conventional Doping for p and n Type Silicon Nanocrystals**  
18.07.2014

23. Marganiec, Justyna  
GSI Darmstadt  
**Coulomb dissociation of Ne-17**  
18.12.2014

24. Migunov, Vadim  
Ernst-Ruska-Zentrum Jülich  
**Studies of electronic and magnetic properties of nanoscaled objects by combination of electron holography and probe microscopy in TEM**  
13.06.2014

25. Murdin, Ben M.  
University of Surrey, Guildford, UK  
**Physics of high field magnetic white dwarf stars – relevance to silicon quantum information applications?**  
24.06.2014

26. Narkowicz, Ryszard  
TU Dortmund, Department of Physics  
**Planar microresonators for ferromagnetic resonance measurements of micro- and nanostructures**  
13.02.2014

27. Nazarov, Alexei  
Institute of Semiconductor Physics NASU, Kyiv, Ukraine  
**Nanowire junctionless SOI transistors: Operation features and electrical characterization**  
13.06.2014

28. Ney, Andreas  
Abteilung für Festkörperphysik/Johannes Kepler Universität Linz, Austria  
**Towards x-ray detected ferromagnetic resonance with broad-band microwave excitation and spatial resolution**  
21.11.2014

29. Norris, Scott  
SMU Dallas, TX, USA  
**Irradiation-induced morphology evolution: In search of a predictive mathematical model**  
23.06.2014

30. Olsson, Pär  
KTH Stockholm, Sweden  
**A study of gamma radiation damage in spent fuel canisters**  
27.08.2014
31. Pasquale, Massimo  
Istituto Nazionale di Ricerca Metrologica (INRIM), Torino, Italy  
**Microwave properties and damping in [Pt/Co] multilayers with perpendicular anisotropy**  
15.01.2014

32. Polushkin, Nikolay  
University of Lisbon, Institute of Materials and Surfaces Science and Engineering, Portugal  
**Formation Mechanisms and Properties of Directly Laser Patterned Magnetic Media**  
09.12.2014

33. Rodríguez, Raul  
TU Chemnitz  
**Surface enhanced Raman spectroscopy**  
28.04.2014

34. Spemann, Daniel  
Universität Leipzig  
**Applications of ion beam modification and analysis in materials science**  
29.01.2014

35. Sukhostavets, Oksana  
CIC nanoGUNE Consolider, Donostia, Spain  
**Low frequency dynamics of magnetic vortices**  
17.03.2014

Projects

The projects are listed by funding institution and project starting date. In addition, the institute has several bilateral service collaborations with industrial partners and research institutions. These activities are not included in the following overview.

European Projects

1. **02/2010 – 01/2014** European Union  
   **LONGLIFE – Long term irradiation embrittlement effects**  
   Dr. E. Altstadt  
   Phone: 0351 260 2276  
   e.altstadt@hzdr.de

2. **01/2011 – 12/2014** European Union  
   **MATTER – Materials testing and rules**  
   Dr. F. Bergner  
   Phone: 0351 260 3186  
   f.bergner@hzdr.de

3. **06/2012 – 05/2015** European Union  
   **CALIPSO – Coordinated access to light sources**  
   Prof. M. Helm  
   Phone: 0351 260 2260  
   m.helm@hzdr.de

4. **01/2013 – 12/2016** European Union  
   **SPRITE – Supporting postgraduate research**  
   Dr. J. v. Borany  
   Phone: 0351 260 3378  
   j.v.borany@hzdr.de

5. **11/2013 – 10/2017** European Union  
   **MatISSE – Materials' Innovations for a Safe and Sustainable nuclear in Europe**  
   Dr. E. Altstadt  
   Phone: 0351 260 2276  
   e.altstadt@hzdr.de

Helmholtz Association Projects

1. **03/2011 – 02/2016** Helmholtz–Gemeinschaft  
   **Functional Materials – Helmholtz Young Investigators' Group**  
   Dr. Shengqiang Zhou  
   Phone: 0351 260 2484  
   s.zhou@hzdr.de

2. **07/2011 – 09/2018** Helmholtz–Gemeinschaft  
   **NANONET – Helmholtz research school on nanoelectronics**  
   Dr. A. Erbe  
   Phone: 0351 260 2368  
   a.erbe@hzdr.de

   **MEMRIOX – Virtual Institute – Memory effects in oxides**  
   Dr. P. Zahn  
   Phone: 0351 260 3121  
   p.zahn@hzdr.de

4. **02/2012 – 01/2015** Helmholtz–Gemeinschaft  
   **HRJRG–DETI.2 – Helmholtz Russia joint research group – Magnetic TiO₂**  
   Dr. K. Potzger  
   Phone: 0351 260 3244  
   k.potzger@hzdr.de

5. **01/2013 – 12/2017** Helmholtz–Gemeinschaft  
   **Professorship TU Chemnitz**  
   Prof. S. Gemming  
   Phone: 0351 260 2470  
   s.gemming@hzdr.de

6. **03/2013 – 02/2014** Helmholtz–Gemeinschaft  
   **HEF–i3membrane – nanopore metal filter**  
   Prof. A. Kolitsch  
   Phone: 0351 260 3348  
   a.kolitsch@hzdr.de

7. **01/2014 – 12/2018** Helmholtz–Gemeinschaft  
   **Spintronics – Helmholtz Young Investigators' Group**  
   Dr. A.M. Deac  
   Phone: 0351 260 3709  
   a.deac@hzdr.de

8. **03/2014 – 02/2017** Helmholtz–Gemeinschaft  
   **HGF Postdoc Dr. Yu Liu – Functional Materials**  
   Prof. M. Helm  
   Phone: 0351 260 2260  
   m.helm@hzdr.de
German Science Foundation Projects

1. 02/2010 – 06/2015 Deutsche Forschungsgemeinschaft
   **HybMagMat – Hybride magnetic materials**
   Prof. J. Fassbender Phone: 0351 260 3096 j.fassbender@hzdr.de

2. 08/2010 – 06/2014 Deutsche Forschungsgemeinschaft
   **SuSi – Superconductivity in heavily doped group-IV superconductors**
   Dr. V. Heera Phone: 0351 260 3343 v.heera@hzdr.de

3. 09/2010 – 07/2015 Deutsche Forschungsgemeinschaft
   **TERATOP – Terahertz non-linear detection and quantum optical studies by resonant two-photon transitions in semiconductor quantum wells**
   Dr. H. Schneider Phone: 0351 260 2880 h.schneider@hzdr.de

4. 11/2010 – 06/2014 Deutsche Forschungsgemeinschaft
   **Atomistic simulation of selforganization by ion-beam erosion**
   Dr. K.-H. Heinig Phone: 0351 260 3288 k.h.heinig@hzdr.de

5. 11/2010 – 12/2016 Deutsche Forschungsgemeinschaft
   **Relaxation dynamics in graphene**
   Dr. S. Winnerl Phone: 0351 260 3522 s.winnerl@hzdr.de

6. 01/2011 – 09/2014 Deutsche Forschungsgemeinschaft
   **Interaction of slow highly charged ions with surfaces**
   Dr. S. Facsko Phone: 0351 260 2987 s.facsko@hzdr.de

7. 01/2011 – 02/2014 Deutsche Forschungsgemeinschaft
   **Selforganized surface patterns on germanium by heavy cluster ions**
   Dr. L. Bischoff Phone: 0351 260 2963 l.bischoff@hzdr.de

8. 03/2011 – 02/2014 Deutsche Forschungsgemeinschaft
   **HISENSE – High-field studies of the band dispersion in novel semiconductor materials**
   Dr. O. Drachenko Phone: 0351 260 3593 o.drachenko@hzdr.de

9. 04/2011 – 06/2015 Deutsche Forschungsgemeinschaft
   **FRUSTPART – Nucleation of spin order in low-dimensional colloidal particle systems**
   Dr. A. Erbe Phone: 0351 260 2366 a.erbe@hzdr.de

10. 08/2011 – 07/2014 Deutsche Forschungsgemeinschaft
    **Nanostructuring of surfaces with direct extraction of ions from plasma sources**
    Dr. S. Facsko Phone: 0351 260 2987 s.facsko@hzdr.de

11. 03/2012 – 06/2014 Deutsche Forschungsgemeinschaft
    **Space-resolved ferromagnetic resonance**
    Dr. J. Lindner Phone: 0351 260 3221 j.lindner@hzdr.de

12. 09/2012 – 09/2015 Deutsche Forschungsgemeinschaft
    **ATOMIX – Atomic mixing in semiconductor layers**
    Dr. M. Posselt Phone: 0351 260 3279 m.posselt@hzdr.de

13. 01/2013 – 12/2015 Deutsche Forschungsgemeinschaft
    **MWN – Magnetization dynamics in nanostructures**
    Dr. J. Lindner Phone: 0351 260 3221 j.lindner@hzdr.de

14. 01/2013 – 10/2017 Deutsche Forschungsgemeinschaft
    **cluster of Excellence – Center for Advancing Electronics Dresden**
    Prof. M. Helm Phone: 0351 260 2260 m.helm@hzdr.de

Doctoral training programme

International Helmholtz Research School NANO NET

The Institute of Ion Beam Physics and Materials Research is coordinating the International Helmholtz Research School for Nanoelectronic Networks (IHRS NANO NET) supported by the Initiative and Networking Fund of the Helmholtz Association. The project started in October 2012. The total funding is 1.2 Mio. € for a period of six years.

The IHRS NANO NET is an international, interdisciplinary and thematically focused doctoral programme in the field of molecular electronics. The research school aims at attracting and promoting excellence by educating promising doctoral candidates with backgrounds in physics, chemistry, materials science and electrical engineering. During a period of three years PhD candidates benefit from well-structured, comprehensive training curricula and multiple mentorship, while performing cutting edge research projects within one of the 14 NANO NET research groups. Under the supervision of outstanding scientists leading the field of nanoelectronics, the doctoral candidates have the unique opportunity to contribute to the advancement of molecular electronics by developing strategies for the real integration of single nanosized building blocks into large interconnected networks.

The period of doctoral studies is crucial in the academic career of young scientists. Therefore, the IHRS NANO NET fosters not only professional qualification but also personal development by equipping young graduates with competencies for successful careers in a wide variety of positions in academia and industry. The training programme invests on professional competencies, such as the capability to work across disciplines and cultures by promoting networking and the exchange of ideas and knowledge with fellows, mentors and collaboration partners. The cooperation with international scientific and industrial partners complements and broadens the expertise of the IHRS NANO NET by establishing a unique research and training network for its doctoral candidates.

The consortium

- Helmholtz-Zentrum Dresden-Rossendorf (HZDR)
- Technische Universität (TU) Dresden
- Leibniz Institute of Polymer Research (IPF) Dresden
- Fraunhofer Institute for Ceramic Technologies and Systems (IKTS) Dresden
- Nanoelectronic Materials Laboratory (NaMLab) gGmbH Dresden

For further information please contact the NANO NET coordinator, Dr. Peter Zahn (nanonet@hzdr.de) or visit the IHRS NANO NET website: www.ihrs-nanonet.de

User facilities and services

Ion Beam Center (IBC)

The Ion Beam Center (IBC) at HZDR combines various machines (electrostatic accelerators, ion implanters, plasma-based equipment) into a unique facility primarily used for ion beam modification and ion beam analysis of materials. The available energy range spans from a few eV to almost 100 MeV with a respective interaction depth in solids between 0.1 nm to 10 µm. In addition to standard broad beams also focused (down to 1 nm) and highly-charged (charge state up to +45) ion beams are provided. In addition to these ion beam facilities, structural analysis (electron microscopy and spectroscopy, X-ray scattering techniques) and sample or device processing under clean-room conditions can be utilized at IBC to deliver a “complete” user service. A schematic overview of the IBC including the description of the main beam lines and experimental stations is given at page 78 of this Annual Report. In 2014 about 12,000 beam time hours were delivered to 350 users from 25 countries worldwide performing experiments at IBC or using the capabilities for ion beam services.

After HZDR joined the Helmholtz Association in 2011, IBC activities have been integrated efficiently into various Helmholtz programmes within the research field “Matter”, but also in the Helmholtz cross-programme activities “Mineral Resources”, “Helmholtz Climate Initiative” and “Materials Research for Energy Technologies”. From the beginning of 2015 the IBC has the status as a Helmholtz LK-II User Facility. Moreover, from 2013 the IBC has been recognized as a large-scale facility within the “BMBF Verbundforschung” program promoting long-term collaborations with universities.

The IBC demonstrates its outstanding status in relation to other international ion beam facilities by the following features:

- The IBC has provided ion beam technology as a user and competence center for ion beam applications for more than 30 years. With respect to user beam time hours the IBC is internationally leading and has been supported by numerous national and European grants and by industry.
- IBC activities cover both ion beam modification as well as ion beam analysis (IBA). Experienced staff is present to support IBC users and to enhance the experimental capabilities to their needs.
• Operation of IBC is accompanied by a strong in-house research at the affiliated host institute, both in experiment and theory. This allows in-depth research in targeted research areas as well as the exploration of new application fields for ion beam technology.

Following the rules of a European and national user facility, access for scientific experiments to IBC is provided on the basis of a proposal procedure (www.hzdr.de/IBC) via the common HZDR user facility portal HZDR-GATE (gate.hzdr.de). Due to the availability of multiple machines and versatile instrumentation, continuous submission of IBC proposals can be offered (no deadline). The scientific quality of the proposals is steadily evaluated and ranked by an external international User Selection Panel (USP). For successfully evaluated proposals, users get free access to IBC facilities for their experiments which can be often realized within three month after proposal submission. The use of the IBC facilities includes the scientific and technical support during planning, execution and subsequent evaluation of the experiments.

The IBC has a strong background in the commercial exploitation of ion beam technology with partners from industry which is essential for materials science applications. For ion beam services the HZDR Innovation GmbH (spin-off of the HZDR) – www.hzdr-innovation.de – provides a direct and fast access to the IBC facilities based on individual contracts. The close collaboration between IBC and HZDR Innovation GmbH is considered as a reference model aiming to develop innovative strategies for an effective contribution of Helmholtz large-scale facilities for economic innovation. Currently, about 20% of the total IBC beam time is used for commercial ion beam services.

The IBC pursues two strategic objectives for further development. On one hand, it is focused on the successful operation as an international user facility to sustain its position as a leading European ion beam center in the fields of materials and interdisciplinary research. This requires the continuous development and extension of ion beam technologies. Special emphasis is directed towards new R&D areas and communities which so far have not been aware of the advantages of ion technology. On the other hand, cutting edge scientific challenges, in particular for the modification and understanding of the function of materials at the nano-scale down to the atomic level, is addressed in order to achieve new functionalities and to design novel materials. These challenges comprise:

• the extended application of low-energy ions for modification and analysis of ultra-thin films, surfaces, 2D materials and molecular layers based on a new Low Energy Ion Nano-Engineering Facility (LEINEF) which is currently projected for first experiments in 2017,

• the investigation of material states and modifications far from equilibrium induced by high-energy density excitations with cluster and highly-charged ions,

• the exploration of new IBA approaches with unprecedented lateral resolution, ultimate detection limit and high sample throughput, e.g. for resource technology. In this context, a fruitful and close collaboration between the IBC and the Helmholtz Institute of Resource Technology (www.hzdr.de/fwg) has been developed during last years. With projects like “High-Speed-PIXE” and “Super-SIMS”, the interdisciplinary work of IBC will be substantially extended towards the application of ion beam analysis methods in geosciences and resource technology.

In 2013, some new ion beam tools or end-stations have been commissioned which will attract new users by cutting-edge experimental instrumentation. As an example, the installation and routine operation of the ion microscope ORION NanoFab (He / Ne ions, 10 - 40 keV) is mentioned enabling unique possibilities for ion imaging and nano-fabrication with feature sizes below 10 nm. The development of ion beam analysis capabilities for this instrument is presently under study.

For more detailed information please contact Dr. Johannes von Borany (j.v.borany@hzdr.de) or Dr. Stefan Facsko (s.facsko@hzdr.de) and visit the IBC webpage: www.hzdr.de/IBC.
Free Electron Laser FELBE

ELBE is an acronym for the free-electron laser (FEL) at the Electron Linear accelerator with high Brilliance and low Emittance (ELBE) located at the Helmholtz-Zentrum Dresden-Rossendorf, Germany. The heart of ELBE is a superconducting linear accelerator operating in cw mode with a pulse repetition rate of 13 MHz. The electron beam (40 MeV, 1 mA max.) is guided to several laboratories where secondary beams (particle and electromagnetic) are generated. Two free-electron lasers (U27-FEL and U100-FEL) produce intense, coherent electromagnetic radiation in the mid and far infrared, which is tunable over a wide wavelength range (4 – 250 µm) by changing the electron energy or the undulator magnetic field. Main parameters of the infrared radiation produced by FELBE are as follows:

<table>
<thead>
<tr>
<th>Wavelength λ</th>

The free electron laser is a user facility. Applications for beam time can be submitted twice a year, typically by April 15 and October 15. Users from EU countries can receive support through the FP7 Integrated Infrastructure Initiative (I3) CALIPSO (Coordinated Access to Light sources to Promote Standards and Optimization).

Typical applications are picosecond pump-probe spectroscopy (also in combination with several other femtosecond lasers, which are synchronized to the FEL), near-field microscopy and nonlinear optics. The FELBE facility also serves as a far-infrared source for experiments at the High-Field Laboratory Dresden (HLD) involving pulsed magnetic fields up to 70 Tesla.

The statistics shows that the FEL used 1670 hours beamtime of the ELBE accelerator. This corresponds to 28 % of total beamtime, which is again distributed among internal and external users.

For further information please contact:
Prof. Manfred Helm (m.helm@hzdr.de) or visit the FELBE webpage www.hzdr.de/FELBE.
ROssendorf BeamLine (ROBL)

Since 1998 the HZDR operates the Rossendorf Beamline at the ESRF. More than 220 days of beamtime are provided for user operation per year. Two experimental stations sharing one beamline optics are available: the station for X-ray spectroscopy of Actinides and other radionuclides (Radio Chemistry Hutch RCH) and the Materials Research Hutch MRH. In 2012, the X-ray optics in the optics hutch was completely replaced. The new monochromator hosts three different sets of crystals and two different sets of multilayers. The higher photon flux of the multilayer is gained by a loss of energy resolution as displayed in the table below. In the energy range of 5 to 11.5 keV an unfocused, parallel beam for high resolution diffraction experiments can be used, while from 9 to 35 keV the synchrotron radiation beam is focused by a toroidal mirror. By the new optics, the beamline gained in general more flexibility allowing to optimize the beamline parameters for each particular experiment.

The majority of MRH experiments is dedicated to the analysis of nano-sized as well as nano-structured materials, thin films, multilayers or the investigation of crystalline phases in low concentration by different X-ray based methods like (anomalous) scattering and diffraction, even spectroscopy is possible. In the center of interest are in-situ investigations of materials under processing or synthesis conditions.

In particular highly specialized sample environments present at MRH need to be mentioned here. A three-port magnetron sputtering chamber is available for in-situ growth and annealing studies using DC and RF sputtering. Additionally one magnetron can be replaced by an ion gun permitting surface irradiation or ion implantation experiments. Thereby the implantation energy can be increased up to 20keV by applying an additional potential. The most requested sample chamber is a furnace equipped with a semispherical Be dome (for vacuum experiments) or with a Kapton window dome (for experiments at atmospheric pressures). The latter setup is dedicated to in-situ measurements operating with different reactive gases like acetylene, hydrogen, ammonia, benzene etc. used in CVD growth processes or hydrogen loading. Furthermore electrical measurements and in-situ X-ray experiments can be combined in these furnaces. Additionally, sample environments provided by users can be integrated in the set-up. All these experiments aim at the correlation of structural properties of materials with their functionality which is the key for a better material understanding.
