Graphical abstract
Abstract:

Torrefaction is a biomass energy densification process that generates a major byproduct in the form of torrefaction condensate. Microbial conversion of TC could be an attractive option for energy integration within torrefaction process. However, TC contains several compounds, such as furfural, 5-hydroxymethylfurfural and guaiacol that are inhibitory to microbes. In this study, for the first time, we reported detoxification of TC, by removing the major inhibitory compound furfural, using torrefied biomass (TB) and later used the detoxified TC for anaerobic digestion. The effect of varying TB production temperature (225–300 °C), TB dosage (25–250 g/L), initial pH (2–9), and contact time (1–12 h) on furfural adsorption was studied with batch adsorption experiments. Mechanism of furfural adsorption on torrefied biomass was best represented by pseudo second order kinetic model. The adsorption of furfural and other inhibitory compounds on TB was likely a hydrophobic interaction. A maximum of 60% of furfural was adsorbed from TC containing 9000 mg furfural/L using 250 g/L of TB in batch adsorption. For, column (20 mm internal diameter and 200 mm bed height), the saturation time for furfural adsorption was around 50 min. Anaerobic digestion of the detoxified TC shows that the lag phase in methane production was reduced from 25 d to 15 d for 0.2 VS_{substrate}:VS_{inoculum} loading. The study shows that TC can be effectively detoxified using TB for microbial conversion and can efficiently be integrated within the torrefied biomass pellet production process.

Key words: Detoxification; Anaerobic digestion; pellets; torrefaction volatiles; Energy densification
1. Introduction

Torrefaction is a pretreatment method for biomass upgradation, where the biomass is heated slowly at a temperature range of 200-300 °C in an inert environment in order to increase the energy density and hydrophobicity by lowering the moisture content of the biomass [1]. In the recent days the research interest on torrefaction process is increasing owing to high commercial demand of torrefied biomass, projected to be 70 million tons per year by 2020 globally [2].

The two major technical challenges in commercialization of torrefaction technology are handling the volatile gases that are produced during the torrefaction and the energy integration within the process [1]. At present, the volatile gases produced are combusted back to meet the energy requirements for biomass drying and torrefaction. However, owing to their high water and CO₂ content, the torrefaction volatiles have low heating value. In addition, presence of different types of organic acids makes them very corrosive to the combusting equipment [1,3] Hence, advanced process integration approaches are required for better utilization of torrefaction volatiles and thereby improving the overall efficiency and economic viability of the torrefaction system [3,4]

The torrefaction condensate (obtained by condensing the volatiles) mainly contains water and acetic acid. Recently, Doddapaneni et al. (2017) [4] reported that torrefaction condensate, with ~50 g/L of acetic acid, can be used as substrate for anaerobic digestion (AD) for bio-methane production. However, owing to the presence of inhibitory compounds such as furfural, 5-Hydroxymethylfurfural (5-HMF) and guaiacol, the methane production was inhibited at higher substrate loading [3]. In order to improve the methane production, concentration of these inhibitory compounds should be significantly decreased in the torrefaction condensate.

Adsorption is a cost-effective method for removal of inhibitory compounds from the pyrolysis oil and biomass hydrolysate [5,6]. Polymeric adsorbents such as XAD-4 and XAD-7 was shown to adsorb 90 and 80 mg of furfural per g of adsorbent from corn fiber hydrolysate [5]. Other study [7] reported that the adsorption of phenol and furfural from oat hull hydrolysate using powdered activated
carbon improved the bioproduction of xylitol by 10%. However, due to the large concentration of furfural (XX g/L) in the torrefaction condensate, a cheap and readily available adsorbent with reasonable adsorption capacity is required. Torrefied biomass could be an alternative adsorbent due to their hydrophobic nature as furfural is also hydrophobic, cost-effectiveness and easy availability (REF). However, there are no studies on the removal of inhibitory compounds from torrefaction condensate using torrefied biomass and the further application of detoxified torrefaction condensate for bioconversion.

Torrefaction process reduces the energy required for biomass grinding but subsequently, it increases the energy requirement for pelletization owing to the increase in the biomass brittleness [8]. The energy required to pelletize the raw biomass and torrefied biomass are in the range of 757 kJ/kg and 1164 kJ/kg respectively [9]. Preconditioning of torrefied biomass with water to a moisture content of 10% [10] or addition of binding materials, such as wheat flour [9], lignin, starch, calcium hydroxide and sodium hydroxide [11,12] has been reported to improve the properties of the pellets. However, this external addition of binders would add to the production cost and also sourcing binders for large production volumes would be challenging [13].

Figure 1 illustrates an integrated process to address the above-discussed issues i.e. (i) microbial inhibition with torrefaction condensate: through torrefied biomass based adsorption of inhibitory compounds, and (ii) the supply of binders for torrefied biomass pelletization: through adsorbed compounds from torrefaction condensate. The proposed approach is to use a part of torrefied biomass as an adsorbent for removal of the inhibitory compounds from the condensate. Following adsorption, the water content and compounds adsorbed on the biomass will themselves add binding effects and thereby could reduce the energy requirement in pelletization [14]. Moreover, the torrefied biomass with compounds adsorbed to them could be mixed with rest of the torrefied biomass before pelletizing, which will improve the quality and durability of the pellets. The torrefaction condensate after adsorption (detoxified condensate) can be used in AD process.
This study focuses on the adsorption and anaerobic digestion stages presented in Fig. 1. Here we used torrefied biomass, for the first time, to adsorb furfural from the torrefaction condensate in order to improve the prospects of utilizing torrefaction condensate in anaerobic digestion. Adsorption of furfural was studied in detail, as it is the major inhibitory compound present in torrefaction condensate [4]; [3]. The adsorption efficiency of torrefied biomass was tested using standard furfural solution by means of batch experiments by varying pH and biomass dosage and further evaluated through kinetic modelling. Further, the batch adsorption experiments were also carried out using actual torrefaction condensate. Later, column experiments were conducted with both standard furfural solution and torrefaction condensate. The break-through curves were determined for furfural and other inhibitory compounds. The empirical models were investigated to decipher the mechanisms of adsorption. Finally, the anaerobic digestion experiments were carried out with both original and detoxified torrefaction condensate.

2. Materials and methods

2.1 Torrefaction process

Torrefied biomass and torrefaction condensate were produced as described by Doddapaneni et al. [4]. Briefly, Finnish pine wood chips were air dried at 105 °C for 24 h in an electrically heated oven. The reactor (Fig. S1) temperature was raised from room temperature (20 °C) to a final torrefaction temperature i.e. 225, 275 or 300 °C and maintained at that temperature for 2 h. The fluctuation in the reactor temperature was maintained within ± 5 °C during the isothermal period by circulating water through the coils wrapped around the reactor. In each run, one kg of biomass was loaded into the reactor. The volatiles released during the torrefaction process were condensed using
water circulated condenser and a glass bottle submerged in an ice bath. The condensate was stored at 4 °C to prevent further aging reactions. The torrefaction condensate has a tendency to form settled tar that is viscous and sticky in nature. This viscous tar (~ 5 vol. %) was removed by simple decantation and the torrefied biomass was grinded using Restsch ZM200 centrifugal mill prior to the adsorption experiments. The grinded biomass was sieved to a particle size of <100 µm.

2.2 Characterization of torrefied biomass

Torrefied biomass was characterized using scanning electron microscopy (SEM) and Brunauer–Emmett–Teller (BET) analysis. Pore size distribution and surface area measurements were evaluated according to Baret-Yoymer-Halenda (BJH) and BET model, respectively.

2.3 Batch adsorption experiments

All the batch adsorption experiments were carried out in a total volume of 20 mL, with continuous mixing at 150 rpm and 20 °C. The kinetics of furfural adsorption using torrefied biomass was studied for 12 h at an initial furfural concentration of 6000 mg/L and pH 3.6, and torrefied biomass concentration varying from 25 - 150 g/L. All the subsequent batch adsorption experiments were carried out for the duration of 12 h as the equilibrium was achieved. For the isotherm study, the initial furfural concentration was varied from 300 - 6000 mg/L with pH of 3.6 and torrefied biomass concentration of 50 g/L. The effect of pH on furfural adsorption was studied by varying the initial furfural solution pH from 2 to 9, with initial furfural concentration of 6000 mg/L and torrefied biomass concentration of 100 g/L. The effect of biomass dosage on furfural adsorption was studied by varying torrefied biomass concentration from 25 - 150 g/L, with initial furfural concentration of 6000 mg/L and pH of 3.6. In case of batch adsorption studies with torrefaction condensate, the torrefied biomass dosage of 25, 50, 100, 200 and 250 g/L was added to 10 mL of torrefaction
condensate. Torrefaction condensate was used at its original pH in all adsorption tests carried out in this study. The solid-liquid separation was achieved by centrifuging the samples at 5018 x g for 5 min. Supernatants were filtered using 0.45 µm (Chromafill® - PET 45/25) prior to gas chromatography mass spectrometer (GC-MS) analysis. All the batch adsorption experiments were carried out in duplicates and if the difference was more than 10%, the experiments were repeated.

2.4. Column adsorption experiments

The column experiments were carried out in glass column of internal diameter of 10 and 20 mm and the length of 300 mm. Borosilicate glass beads (2 mm dia) were used to pack torrefied biomass from top and bottom in the column. This glass bead packing (2 cm height) was also helpful in allowing uniform distribution of the adsorbate in the column by preventing backlash. The effective bed height of adsorbent (i.e. torrefied biomass) was 200 mm. The amount of torrefied biomass filled in 10 and 20 mm columns were 7 g and 20 g, respectively. Either the standard furfural solution with 6000 mg/L with initial pH of 3.6 or the torrefaction condensate were loaded into column using peristaltic pump at 1 mL/min. Aliquots from the column were collected every 5 min for GC-MS analysis. Control experiments with borosilicate glass beads were carried out to rule out adsorption of furfural on them.

2.5. Anaerobic digestion (AD) batch assay

The AD batch assays of torrefaction condensate before and after detoxification was studied, using 120 mL serum bottles at mesophilic condition i.e. 35 °C for 35 d. The operating volume was 60 mL. The substrate to inoculum ratio (VS<sub>substrate</sub>:VS<sub>inoculum</sub>) of 0.1 (non-inhibitory concentration) and 0.2 (inhibitory concentration) were tested. Granular sludge collected from the mesophilic upflow anaerobic sludge blanket (USAB) reactor that treats waste water from an integrated beta-amylase and
ethanol plant (Jokioinen, Finland) was used as inoculum for AD batch assays. Detailed methodology has been previously reported [4].

2.6 Analytical methods

Surface characteristics of torrefied biomass was analyzed using scanning electron microscopy JSM –T10 (Jeol, USA). Specific surface area (SSA) and pore size distributions were measured using a Micrometrics ASAP 2020 (Norcross, USA) by physical adsorption of nitrogen. For adsorption tests, about 100 mg of sample was loaded into a quartz tube. Prior to adsorption tests, contaminating gases from samples were removed using 10 µm Hg at a temperature of 150 °C. Detailed methodology has been reported by Kramb et al. (2017) [15].

Gas chromatograph (GC; Agilent series 6890) equipped with mass spectrometry (MS) detector (Agilent 5975B) and the capillary column HP-5MS (30 m, 0.25 mm ID, 0.25 µm film thickness; Agilent) was used to analyze both standard furfural solution and torrefaction condensate before and after adsorption experiments. In case of standard furfural solution, initially the GC column was held for 2 min at 50 °C, and followed by a ramp of 5 °C/min to a temperature of 250 °C. Later, the oven was heated to a final temperature of 280 °C at 10 °C/min and held for 10 min. The helium gas with a flow rate of 1 mL/min was used as a carrier gas. The injection temperature was 250 °C. The injection volume was 0.2 µL with a split ratio of 20:1. In case of torrefaction condensate analysis, the oven temperature was raised at a heating rate of 2 °C/min to a temperature of 180 °C and then to a final temperature of 280 °C at 10 °C/min. The oven was held at final temperature for 5 min. The MS temperature was maintained at 250 °C.

The total solids (TS) and volatile solids (VS) of the inoculum and the torrefaction condensate was tested as described by Doddapaneni et al. [4]. The methane production was tested using GC following the procedure described in our earlier study [4].
3. Results

3.1 Characterization of the adsorbent (torrefied biomass)

Figure 2 shows SEM images of the pine wood biomass torrefied at 225, 275 and 300 °C. It can be observed that the porosity of biomass is increasing with increasing torrefaction temperature. At temperature 225 °C, no specific surface area (SSA) and pore diameter was detected by the BET analysis (Table 1). The further increase in temperature to 275 °C led to increase in SSA. However, SSA decreased with further raise in temperature to 300 °C.

3.2 Characterization of torrefaction condensate

Torrefaction condensate mainly contains water, organic acids, aldehydes and phenolic compounds. The pH of torrefaction condensate was around 2.1. The concentration of acetic acid, furfural were, 80 and 9 g/L, respectively for the torrefaction condensate produced at 300 °C. The VS was around 11%.

3.3 Influence of torrefaction temperature on furfural adsorption

The influence of torrefaction temperature to produce torrefied biomass on furfural adsorption was studied (Figure S2 in supplementary Information). Furfural adsorption (%) increased from 47% at 225 °C to 77% at 300 °C with 150 g torrefied biomass/L. Because of the higher adsorption, the torrefied biomass produced at 300 °C was used in all our adsorption experiments.

3.4 Batch adsorption of furfural

3.4.1 Kinetic study
The influence of contact time was studied by varying the reaction duration from 1 to 12 h (Fig. 3a). The adsorption of furfural was relatively fast and more than 85% of maximum \( q_e \) (mg of furfural adsorbed per g of torrefied biomass) was achieved in first 2 h. The kinetic analysis of the adsorption of furfural on torrefied biomass was made using pseudo first order and second order kinetic models (Add references for these equations – May be a review paper) (more details in supplementary information).

The plot of \( \log (q_e - q_t) \) versus \( t \), the plot of \( q_t/t \) versus \( t \) represents the first order and second order kinetic models respectively. The rate constants (\( k_i \)), and (\( k_s \)), for first and second order kinetic models, respectively were presented in Table 2. From Fig. 3b and Table 2 it can be observed that the pseudo second order model fits well with the \( R^2 \) values greater than 0.99. The variation between the calculated \( q_e \) \( \text{cal.} \) and the experimental \( q_e \) values were varying between 17 - 51% and 6 - 8% for pseudo first order and second order kinetic models, respectively further suggesting better fit for pseudo second order kinetic model.

The rate constant of pseudo second order kinetic model is a combination of external mass transfer, film diffusion and intra-particle diffusion. Thus, the adsorption of furfural on to torrefied biomass was further studied to identify the rate limiting step in the process. The external mass transfer model, furfural transfer across the boundary layer (Boyd’s film diffusion model), intra-particle diffusion (Webber-Morris) and pore diffusion model (Bangham’s model) were tested.

The mass transfer of adsorbate from the bulk solution to the boundary layer could be a rate limiting step and this was analyzed using the mass transfer model represented by equation 1.

\[
\frac{d(C_t/C_0)}{dt} = -\beta \frac{L}{S} \quad \text{(1)}
\]
where $\beta_L$ is the external mass transfer coefficient. Fig. 3c represents the plot of mass transfer model i.e. $C_t/C_0$ versus $t$. The external mass transfer coefficient ($\beta_L$) was calculated from the slope of the same plot. The $\beta_L$ values varied from $2 \times 10^{-4}$ which were two orders and eight orders of magnitude lower than the adsorption of Cd onto elemental selenium nanoparticles [16] and the adsorption of Cu onto dried activated sludge [17]. The lower values shows that the external mass transfer is not the rate limiting step (Table 2) [16].

Film diffusion model or Boyd’s kinetic model (Eq. 2) was used to identify whether the diffusion of adsorbate across the boundary layer was a rate-limiting step.

$$
\ln \left[ \frac{1}{(1 - F^2(t))} \right] = \frac{\pi^2 D_et}{r^2} \quad \text{(2)}
$$

Where $F(t) = q_t/q_e$; $D_e$ is the effective diffusion coefficient (m$^2$/s); $r$ is the radius of the spherical adsorbent particle [18]. If the plot of $\ln \left[ \frac{1}{(1 - F^2(t))} \right]$ vs $t$ is a straight line and passing through the origin then the film diffusion is the rate limiting step [18]. Previous study [19] reported that the spherical equivalent diameter of the torrefied biomass sieved to a particle size of 112 – 125 $\mu$m was 200 $\mu$m. According to that, it was assumed that the torrefied biomass particle is spherical with a particle diameter of 150 $\mu$m. The internal diffusion coefficient ($D$) was calculated from the slope of the plot presented in Fig. 3d. From the same figure, it can be observed that the plots do not pass through the origin (intercept of X, Y, Z and t for 25, 50, 100 and 150g/L), showing that the diffusion of adsorbate across the boundary layer is the rate-limiting step in case of adsorption of furfural on to the torrefied biomass.

The intra-particle diffusion model (Eq. 3) was used to identify the transfer of furfural from the external surface of the adsorbate to sites through pores of the torrefied biomass.

$$
q_t = k_{id} t^{1/2} + C \quad \text{------------------- (3)}
$$
where $q_t$ is the equilibrium adsorption (mg/g) at time $t$ and $k_{id}$ is the intra-particle diffusion rate constant. The multi-linear plots (with average $R^2 > 0.97$ for the first and second zone) represents that the adsorption is controlled by two mechanisms (Figure 3e, Table 2). The first stage of the intraparticle diffusion model (webber-Morris graph) represents the external mass transfer and the second stage represents the diffusion [20]. The first linear phase lasted for 2 h while the second linear phase lasted for another 10 h (Figure 3e). The intercept of the first linear zone is also quite small (intercept = XX), suggesting that the intraparticle diffusion is the rate-limiting step.

The rate-limiting step of intraparticle diffusion was also evaluated by Bangham’s kinetic model represented by equation 4.

$$\log \log \left[ \frac{C_o}{C_o - q_t m} \right] = \log \left( \frac{k_b m}{2.303 V} \right) + \alpha \log(t) \quad \text{(4)}$$

where $C_o$ is the initial concentration of the adsorbate (mg/L), $V$ is the volume of solution (L), $m$ is the mass of the adsorbent (g/L), and $k_b$ and $\alpha$ are the constants. The linearity of the plot between $\log \log \left[ \frac{C_o}{C_o - q_t m} \right]$ versus $\log(t)$ represents that pore diffusion is the rate limiting step. The average $R^2 > 0.96$ was observed for all the dosage experiments. The reasonable linearity of Bangham model and second zone of intraparticle diffusion model combined with lower $\beta L_S$ values and non-zero intercept of Boyd’s model comsugggest that the furfural diffusion in the pores of torrefied biomass is the rate limiting step.

### 3.4.2 Effect of pH and dosage

The influence of pH on the adsorption was studied by varying pH from 2.0 to 9.0 (Fig. 4a). The $q_e$ (mg of furfural adsorbed per g of torrefied biomass) value did not vary significantly (<10%) i.e. from 41 (± 4.3) to 37 (± 2.6) when the pH was increased from 2.0 to 9.0, respectively. During these experiments, the equilibrium pH varied from XX to ZZ. The effect od dosage on furfural
adsorption was studied by increasing the dosage from 25 to 150 g/L of torrefied biomass, at 12 h of residence time. The furfural removal increased from 17 (at 25 g/L) to 77% (150 g/L) (Fig. 4b). The $q_e$ values were 41 ($\pm$ 3.41) and 31 ($\pm$ 0.61) (mg of furfural adsorbed per g of torrefied biomass) for 25 and 150 g/L dosage, respectively, at 12 h of residence time.

<Figure 4>

**3.4.3 Adsorption isotherms**

The variation of $q_e$ (mg of furfural adsorbed per g of torrefied biomass) with the equilibrium concentration of furfural (Figure 5a) When the initial concentration was varied from 300 to 6000 mg/L the $q_e$ of furfural onto torrefied biomass was increased from 4.1 ($\pm$ 0.13) to 36.9 ($\pm$ 3.2) (mg of furfural adsorbed per g of torrefied biomass), respectively. The maximum $q_e$ value (i.e. 38 mg of furfural adsorbed per g of torrefied biomass) was observed at an initial concentration of 5500 mg/L.

<Figure 5>

The isotherms were modeled using the linearized Langmuir (equation 5) and Freundlich models (equation 6).

$$\frac{C_e}{q_e} = \frac{C_e}{q_m} + \frac{1}{k_L q_m} \quad \text{------------------ (5)}$$

$C_e$ is the equilibrium concentration of the furfural (mg), $q_e$ (mg of furfural adsorbed per g of torrefied biomass) is the amount of furfural adsorbed at equilibrium (mg/g), $q_m$ is the monolayer adsorption capacity or the maximum adsorption capacity (mg of furfural adsorbed per g of torrefied biomass). $k_L$ is the Langmuir constant which represents adsorption energy (L/g).

$$\ln q_e = \ln k_f + \left(\frac{1}{n}\right) \ln C_e \quad \text{------------------ (6)}$$

Where $k_f$ is adsorbent capacity ((mg/g) (L/mg)) $^{1/n}$ and n is the intensity of the adsorption.
Figure 5b and Figure 5c shows the linear fitting between concentration ($q_e$) and the equilibrium concentration ($c_e$) for Langmuir and Freundlich models respectively. The evaluated constants are presented in Table 3. It was observed that both the Freundlich model fitted better with $R^2$ of 0.98 compared to 0.94 for Langmuir model. The Freundlich constants $k_f$ and $n$ were 0.274 (mg/g) (L/g) and 1.654 respectively suggesting favorable adsorption.

3.5 Batch adsorption of torrefaction condensate

Figure 6 shows adsorption (%) of different compounds from torrefaction condensate at 250 g/L of torrefied biomass dosage. The torrefied biomass adsorbed up to 54% of furfural from the torrefied condensate. Hydroxymethylfurfural (5-HMF), another important inhibitor present in torrefaction condensate, was also adsorbed up to 25%. Around 23% and 60% of furans such as 2(5H)-furanone and 5-methyl-2-furancarboxaldehyde were adsorbed, respectively. In case of phenolic compounds, 74% of coniferyl aldehyde was adsorbed. Around 52, 47 and 56% of other phenolics such as guaiacol, creosol, and vanillin were adsorbed, respectively. In case of organic acids, 21% of formic acid and just 11% of acetic acid was adsorbed. In contrast, concentration of propionic acid was increased by 12%.

<Figure 6>

3.6 Column adsorption study

3.6.1 Column adsorption of standard furfural solution

Column adsorption studies of aqueous furfural solution was carried out at two different column diameters i.e. 10 and 20 mm. The furfural uptake and the time required to reach adsorption saturation was increased with increasing column diameter.
In case of 10 mm diameter column (Fig. S5a in Supplementary Information) the breakthrough time (i.e. \( C/C_0 > 2\% \)) was 10 min and the saturation time (i.e. \( C/C_0 > 95\% \)) was around 80 min. The breakthrough time and saturation time in 20 mm diameter column (Fig. S5b) was around 150 and 380 min respectively. This analysis shows that 20 mm diameter column will be more effective for adsorption of inhibitory compounds from torrefaction condensate. Hence, the column with 20 mm diameter and 200 mm bed length was considered for the column adsorption of torrefaction condensate.

### 3.6.2 Column adsorption of torrefaction condensate

Figure 7 represents the breakthrough curves of different compounds present in torrefaction condensate. The adsorption (%) presented in Fig. 7 were based on the differences in GC-MS peak area of the respective compounds before and after adsorption.

The maximum adsorption of furfural observed was 60% and the saturation time was 50 min. From Fig. 7b, it can be observed that 5-HMF reached saturation within 5 min. The maximum adsorption for other furans such as 5-methyl-2-Furancarboxaldehyde, and 2(5H)-Furanone was 61 and 28% and the saturation time was 50 and 30 min, respectively.

All the phenolic compounds followed similar adsorption pattern. Similar to the batch experiments, coniferyl aldehyde had highest adsorption of 64%. At the same time, vanillin has the least adsorption (30%). Coniferyl aldehyde has the highest saturation time (90 min) than other compounds reported in this study. The maximum adsorption of other phenolic compounds such as guaiacol, cresol and vanillin was 48, 43 and 30% and the saturation was around 50, 30 and 15 min, respectively.

The breakthrough curves of organic acids in torrefaction condensate such as formic, acetic and propionic acids were shown in Fig. 7c. The maximum adsorption of formic acid was around 60%,...
which was higher than in batch adsorption (20%). Whereas, only around 5% of acetic acid has been adsorbed. The changes in the concentration of acetic acid during time course (between 50-150 min) could be possibly due to a tradeoff between their methyl ester counterparts (as seen in Fig. 7d) and not because of actual adsorption on to the torrefied biomass. Moreover, finally we were able to retain 95% of acetic acid in the condensate after 180 min of column adsorption. In case of propionic acid; the column adsorption study followed the batch adsorption by resulting in slight increase in their concentration (~17% after 180 min) possibly due to decrease in water content.

The concentrations of other compounds such as 2-propanone, 1-hydroxy- (acetol) and 1-hydroxy-2-butanone were more stable and no adsorption of these compounds was observed. In addition to these two compounds, hydroxy-acetaldehyde was least adsorbed (< 1% at 50 min) by torrefied biomass.

3.7 Anaerobic digestion batch assay

The torrefaction condensate, detoxified with 250 g/L of torrefied biomass dosage was used in AD batch assays. Figure 8 shows the cumulative methane yield from AD of torrefaction condensate before and after adsorption at the end of 35 d for 0.1 and 0.2 VS\textsubscript{substrate}:VS\textsubscript{inoculum} loadings. The respective methane yield (mL/g VS) for torrefaction condensate before and after detoxification was 689 and 695 for 0.1 VS\textsubscript{substrate}:VS\textsubscript{inoculum} and 699 and 487 for 0.2 VS\textsubscript{substrate}:VS\textsubscript{inoculum}.

<Figure 8>

4. Discussion

4.1 Effect of adsorption of furfural on to torrefied biomass

This study, for the first time, demonstrated adsorption of furfural from torrefaction condensate using torrefied biomass in order to make torrefaction condensate more suitable and less toxic for
microbial bioconversion. About 60% of furfural has been adsorbed from the torrefaction condensate, meaning the reduction in furfural from 9000 to 3600 mg/L at 250 g/L dosage. We have handled very high concentrations of furfural when compared to the studies dealing with biomass hydrolysates, typically in range of 200–3000 mg-furfural/L [5–7,21]. Eventhough we have used high dosage of torrefied biomass as adsorbent, this will not have a negative impact on the overall process considering the fact that the adsorbent is from the same streamline (torrefied biomass pellet production) and following adsorption, they will be mixed back with the rest of the torrefied biomass and taken for regular application. Moreover, no wastes will be generated out of this process.

Björklund et al. [21] studied the removal of fermentation inhibitors from spruce wood hydrolysate using the lignin as an adsorbent and was able to remove 49% of furfural, 27% of 5-HMF and 36% of phenols at 100 g/L of lignin dosage. These values were close to the ones reported in this study for example, removal of 34% of furfural, 14% of 5-HMF and 33% of phenols with 100 g/L torrefied biomass. These values have been achieved in this study inspite of having the initial concentrations around 10 times higher than the ones reported earlier [21]. Monlau et al. [22] studied the applicability of pyrolysis chars produced from solid anaerobic digestion digestate to remove the inhibitory compounds from Douglas-fir wood hydrolysate. They reported that 99% of furfural and 95% of 5-HMF was removed from the hydrolysate at 60 g/L dosage and 24 h contact time where initial concentration of both the compounds was 1000 mg/L suggesting q_e (mg of furfural adsorbed per g of adsorbent) of 16.6 mg/g. This value is lower than the one obtained for torrefied biomass (36.9 ± 3.2 mg/g). Further, using torrefied biomass for adsorption of these compounds would have multiple benefits within the refinery. Firstly, removing inhibitory compounds from the condensate will allow them to be utilize for biomethane production. Secondly, increasing moisture content of the biomass and compounds adsorbed onto the biomass would be useful in later stages of refinery in improving the biomass pelletization.
4.2. Mechanism of adsorption of furfural on torrefied biomass

The adsorption of main inhibitory compound furfural on torrefied biomass is likely due to hydrophobic interaction. The non-effect of pH on the adsorption of furfural points in the direction of hydrophobic interaction (Fig. 5). As the pH varies from 2.0 to 9.0, the deprotonation of the biomass would take place and thus, increasing the number of charged sites. However, the increase in the number of charged sites had no effect on the adsorption of furfural on the torrefied biomass suggesting non-electrostatic mechanisms. Furthermore, adsorption of hydrophobic compounds such as furfural and phenols while non-adsorption of hydrophilic compounds such as acids suggest the adsorption by means of hydrophobic interaction. In addition, the surface of the torrefied biomass is hydrophobic because of the reduced oxygen content [1] further suggesting the hydrophobic interaction between furfural and torrefied biomass. Indeed, the adsorption of furfural from pine needle hydrolysates on to polystyrene-divinylbenzene (XAD-4) copolymers has described as a hydrophobic interaction [23].

As the hydrophobic interactions are spontaneous, the adsorption of furfural on to the hydrophobic sites on the torrefied biomass would be quite fast. This is also supported by the good fitting of kinetic data to the pseudo second order kinetics, suggesting that the adsorption mechanism is mainly chemisorption i.e. a fast favorable reaction with negative $\Delta G$ (Gibbs Energy).

Prior to the adsorption of furfural to the hydrophobic sites in the torrefied biomass, furfural has to reach in close proximity of the sites from the bulk solution. This is done in three steps – arriving of furfural from the bulk solution to the boundary layer, transfer of furfural from the boundary layer to the external surface of torrefied biomass passing through the film or boundary layer and diffusion of furfural to the hydrophobic adsorption site [24]. The reasonable linearity of the second stage intraparticle diffusion model (Fig. 3e) (average $R^2>0.97$) and Bangham model (Fig. 3f) (average $R^2>0.96$) and the plots not passing through the origin for film diffusion model (Fig. 3d) points out that the furfural passage through micropore diffusion in the torrefied biomass is rate-limiting steps. However, further controlled experiments are required to confirm this finding.
The reason for the micropore diffusion to be the rate limiting step can be due to the hydrophobic nature of both furfural and torrefied biomass. As the torrefaction condensate is predominantly made of water (water content > XX%), the furfural molecule, being hydrophobic, will be in cluster. The external surface of the torrefied biomass would have minimized the hydrophobic sites present or only hydrophilic sites would be present. The bulk of the hydrophobic sites would be present more deep in the torrefied biomass. This would result in the need for furfural to diffuse from the external site to internal hydrophobic sites. This is well reflected in diffusion being rate-limiting step in intraparticle diffusion model and Bangham model.

4.3 Torrefaction temperature effect on to the adsorption property of torrefied biomass

At a temperature of 225 °C, a minor portion of hemicellulose is degraded and the volatiles are mainly H₂O and CO₂, which could have caused the low pore distribution on torrefied biomass [26]. As the severity of the torrefaction increases (for example at 275 °C) the further degradation of hemicellulose and minor portion of cellulose and lignin occurs, which increases the release of volatiles and thereby increases the micro pores. According to Reza et al. [12] and Chen et al. [26], it is because the precipitated tar plugs the existing pores to generate new pores and thereby results in the decreased pore size and increased surface area. However, as the temperature further increases to 300 °C, the existing pores are widen and enlarged which results in the decreased surface area (Fig. 1 and Table 1). The adsorption of furfural increases with the increasing torrefaction temperature and this could be mainly because of the enlarged pores or increase in number of sites or both. Further, as the severity of the torrefaction increases, the existing pores on the biomass will enlarge and the these enlarged pores allows the furfural solution to diffuse more rapidly into torrefied biomass structures and thereby increases the surface contact. The higher adsorption of furfural by torrefied biomass produced at 300°C with larger pore size and increased diffusion also reflect that the micropore diffusion is involved in adsorption mechanism.
4.4 Anaerobic digestion of torrefaction condensate

The preliminary study on AD of detoxified torrefaction condensate showed that the proposed adsorption process has improved the methane production. As expected, no inhibition was observed at 0.1 VS$_{\text{substrate}}$:VS$_{\text{inoculum}}$ loading and the methane production was similar for both detoxified and orginal torrefaction condensate for the initial 5 d. However, the methane production with detoxified torrefaction condensate started increasing rapidly after 5 d in comparison with orginal condensate. After 20 d, methane production saturated for both the setups with around 700 mL/g VS. In case of 0.2 VS$_{\text{substrate}}$:VS$_{\text{inoculum}}$ loading, owing to the inhibitory concentrations of compounds in torrefaction condensate, there was a prolonged lag phase (25 d) for methane production in case of original condensate. Whereas, as a result of adsorption, the detoxified condensate started produced methane just within 15 d, ie. 10 d faster than with the orginal condensate. At the same time methane production was higher in case of detoxified condensate (699 mL/g VS) than with orginal condensate (487 mL/g VS) at the end of 35 d. The methane yield from torrefaction condensate reported in this study (700 mL/g VS) is comparable with substrates such as used vegetable oil (648 mL/g VS) [27] and co-digestion of 60% of grease traped sludge with 40% sewage sludge (845 mL/g VS) [28].

Eventhough, methane production is better with detoxified condensate, the lag phase for methane production is still longer with 0.2 VS$_{\text{substrate}}$:VS$_{\text{inoculum}}$ loading when compared with 0.1 VS$_{\text{substrate}}$:VS$_{\text{inoculum}}$ loading. This could be because of only partial removal of inhibitory compounds from the torrefaction condensate. For example, around 3600 mg/L of furfural was present in the condensate even after adsorption. According to [29], the furfural concentration at 2000 mg/L could inhibit the AD process and increases the lag phase. Further decrease in the furfural concentration could be possibly achieved through a sequential batch/column adsorption. Nevertheless, Doddapaneni et al. [4] reported that microbes could be adapted through cyclic batch AD to decrease the lag phase in methane production. Thus, improving the methane production with little or no lag
phase, with higher dosages of torrefaction condensate, is possible and this could be a subject of further investigation.

4.5 Adsorption scale-up

The torrefaction plant capacity proposed by Pirragila et al. [30] i.e. 200 000 ton of torrefied biomass/annum with 8400 operating hours was considered here to understand the flow rate of torrefied biomass in an industrial scale torrefied biomass plant. If it is assumed that 50% of torrefied biomass goes to adsorption process and 50% goes directly to the pelleting section, then 285 ton of torrefied biomass need to be handled at adsorption section per day (24 h). The bulk density of torrefied wood is between 200 – 400 kg/m$^3$ [31]. Considering the bulk density of 300 kg/m$^3$, a total volume of 952 m$^3$ is required for column adsorption for everyday operation. Handling such a high amount of biomass in column could be difficult and also may increase the capital, operational and maintenance expenses of the torrefaction unit. At the same time, column experiments result from this study shows that furfural adsorption reached to saturation at 50 min in case of 20 mm internal diameter and 300 mm length column with a flow rate of 1 mL/min. This shows that the saturation time for torrefied biomass for furfural adsorption from torrefaction condensate at an initial concentration of 9000 mg/L is very low. This low saturation time results in frequent loading and unloading of the torrefied biomass in column. As the torrefied biomass pellets are continuously produced, the continuous operation of adsorption and desorption is not suitable for the proposed integrated approach (Fig. 1). So, column adsorption for the detoxification of torrefaction condensate may not be suitable to integrate with torrefied biomass pellets production.

The experimental results for batch adsorption shows that furfural adsorption is spontaneous for first 2 h of contact time i.e 54 % of furfural removal at an initial concentration of 6000 mg/L. The loading and unloading of the torrefied biomass to the adsorption vessel could be easier and it could
be easily integrated with the existing torrefaction unit. At the same time the operational expenses for batch adsorption are lower in comparison with column operation [32]. Thus, the batch adsorption could be more feasible to integrate with torrefaction process in the proposed approach (Fig. 1). However, a maximum of 60% of furfural was adsorbed from torrefaction condensate containing 9000 mg furfural/L at 250 g/L of torrefied biomass dosage. Indeed, the increased lag phase in case of 0.2 VS_{substrate}:VS_{inoculum} loading in anaerobic digestion of detoxified torrefaction condensate shows that torrefaction condensate still inhibits the methane production. Thus, a series of adsorption systems would be required for the complete removal of inhibitory compounds from torrefaction condensate. The size of the torrefaction plant may also show significant influence on the selection between batch and column adsorption. However detailed techno-economic analysis will be required to select between batch and column adsorption processes for the proposed detoxification approach, and this could be a subject of further investigation.

5. Conclusion

In this study, for the first time, torrefaction condensate was detoxified using torrefied biomass in order to use them as a substrate for methane production. The removal of furfural and other inhibitory compounds was achieved and better methane production by detoxified torrefaction condensate was demonstrated. The pseudo second order kinetics suggesting a hydrophobic interaction between furfural and torrefied biomass was argued. Intraparticle diffusion model and Bangham model combined with effect of torrefaction temperature on furfural adsorption onto torrefied biomass points to micropore diffusion as a rate limiting step. Further, a continuous column detoxification of torrefaction condensate was operated and a way for process integration of this was discussed.
